Preface

The AIEE *Transactions* for 1955 (volume 74) is published in three parts: Part I. Communication and Electronics; Part II. Applications and Industry; and Part III. Power Apparatus and Systems. The papers in each of the three parts are classified according to subject matter as follows:

Part I. Communication and Electronics

- Communication Switching Systems
- Communication Theory
- Radio Communications Systems
- Special Communications Applications
- Telegraph Systems
- Television and Aural Broadcasting Systems
- Wire Communications Systems
- Basic Sciences
- Computing Devices
- Dielectrics
- Electrical Techniques in Medicine and Biology
- Electronics
- Instruments and Measurements
- Magnetic Amplifiers
- Metallic Rectifiers
- Nucleonics
- Solid State Devices

Part II. Applications and Industry

- Air Transportation
- Domestic and Commercial Applications
- Land Transportation
- Marine Transportation
- Production and Application of Light
- Chemical Industry
- Electric Heating
- Electric Welding
- Feedback Control Systems
- General Industry Applications
- Industrial Control
- Industrial Power Rectifiers
- Industrial Power Systems
- Mining and Metal Industry
- Petroleum Industry

Part III. Power Apparatus and Systems

- Carrier Current
- Insulated Conductors
- Power Generation
- Protective Devices
- Relays
- Rotating Machinery
- Substations
- Switchgear
- System Engineering
- Transformers
- Transmission and Distribution

- Education
- Safety
- Research

Each part has been indexed separately in the back of that particular part. The three parts are not cross-referenced; hence the user should determine first whether the subject matter of the paper desired is in the field of communication and electronics, applications and industry, or power apparatus and systems. Papers are listed in the subject index under several key words in the titles. The original numbers assigned to the papers are given in the author index. Volume 74 contains the technical papers and related discussions presented at these meetings:

1. Winter General Meeting, New York, N. Y., January 31–February 4, 1955.
2. Southern District Meeting, St. Petersburg, Fla., April 13–15, 1955.
3. Middle Eastern District Meeting, Columbus Ohio, May 4–6, 1955.
4. Summer General Meeting, Swampscott, Mass., June 27–July 1, 1955.
5. Pacific General Meeting, Butte, Mont., August 15–17, 1955.
6. Fall General Meeting, Chicago, Ill., October 3–7, 1955.

Statements and opinions given in the papers and discussions published in *Transactions* are the expressions of the contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Communication and Electronics Index for 1955

1. Technical Subject Index

A-C Electromotive-Force Transducer and Its Application to Null-Type Recorders, An Angular Position. Guptill, McCarty....610–13
A-C Operated Repeater for 12-Channel Open-Wire Carrier Systems, A Pole-Mounted. Searle, Schaefer....791–5; disc. 795
A-C Servo Applications, Transistor Demodulator for High Performance Magnetic Amplifiers in. Decker....121–3
A-C Windings, A Circuit for Measuring the Resistance of Energized. Seely....214–17; disc. 217
Accurate Electronic Tracer for Dynamic Characteristics of Magnetic Materials, An. Kittl....407–18
(ACSR) for Railroad Signal and Communications Circuits, Aluminum Conductor Steel-Reinforced. Adams....627–9
Admittance, Rapid Measurement of Impedance and. Salzberg, Marini....180–6
Aging Characteristics as Measured by Shearing Modulus, Insulation. Whitman, Scheideler.232–8; disc. 238
Aging Tests on Flexible Sheet Insulation, Significant Factors in Thermal. Dakin, Philofsky, Divens....289–92; disc. 292
Air-borne Temperature Indicator, An. Clark, Amey, Mergner....1–5
Air Traffic Control, Data Transfer and Display Equipment for a Proposed System of. Fenimore..145–9
Air Traffic Control Information, An Electronic System for. Kalb....152–5
All-Magnetic Audio Amplifier System, An. Suozzi, Hooper....297–300; disc. 300
Aluminum Conductor Steel-Reinforced (ACSR) for Railroad Signal and Communications Circuits. Adams....627–9
Aluminum Die Castings for Carrier Telephone Systems. Pedersen....434–9
Amplifier, A Fast Response Magnetic Servo. Kallander....49–54
Amplifier System, An All-Magnetic Audio. Suozzi, Hooper....297–300; disc. 300
Amplifiers, On the Equivalent Circuits of Linear. Vallese....691–4
Amplitude-Modulated Signals, Transfer Functions for. Hellerman....729–31
An Elliptical Polarization Synthesizer. Friedman....339–43; disc. 343
Analogue Divider, A Static Magnetic Transistor. Schaefer....652–5; disc. 655
Analogues Through Conformal Mapping, Improving Field. Farr, Keen....395–400; disc. 400
Analysis and Design of a Magnetic Frequency Multiplier. Smith, Salihi....99–106
Analysis of a Triode Oscillator with Losses Associated with the Inductive Branch and Signal Applied in Grid Circuit. Mostafa....777–81
Analysis of Nonlinear Coupled Circuits. Part II. Ku....439–43
Analysis of Optimum Core Configurations for Magnetic Amplifiers Using a Simplified Approach, An. Bedford, Willis, Dodson....62–70
Analyzer Operation, Computer for Automatizing Network. Kusko, Heller....208–13; disc. 213
Angular Position A-C Electromotive-Force Transducer and Its Application to Null-Type Recorders, An. Guptill, McCarty....610–13
Application of Perpendicularly Superposed Magnetic Fields, The. Heartz, Buelteman..655–9; disc. 659
Appraisal of Delays in Gate-Type Operation, The. Molnar....475–85
Asymmetrical Type, Magnetic Amplifier Sequential Circuits of the. Fitzgerald....685–91
Asymmetry Zero-Drift Errors in Magnetic Servo Amplifiers, Elimination of. Geyger....239–44; disc. 244
(Atlantic) A Transatlantic Telephone Cable. Kelly, Radley, Gilman, Halsey....124–36; disc. 136
Atmospheric Electrostatic Potential, Measuring and Recording. Carroll, Hammond, Stewart..517–20
Audio Amplifier System, An All-Magnetic. Suozzi, Hooper....297–300; disc. 300
Audio-Frequency Range, An Envelope Delay-Measuring Instrument in the. Cannon....710–17
Audio-Frequency Transistor Power Supply, Operational Magnetic Amplifier with. Decker, Gourash.490–6
Audio Telegraph Carrier Terminal, A New. Higgins, Gilbert....58–62
Automatic Field Plotter, An. Gelfand, Shinn, Tuteur....73–8
Automation by Signal Control, Textile. Casper..176–80
Automatizing Network Analyzer Operation, Computer for. Kusko, Heller....208–13; disc. 213

B

Balance for the Measurement of Small Torques, A Precision Torque. Matthys....485–90
Basic Problems in Film Pickup for Television Broadcasting. Gore....462–6
(Basic Sciences) A Continuous-Flow Moisture Detector. Beavers, Shimanski, Timpane.....361–6; disc. 366
(Basic Sciences) A Method for Evaluation of Thermal Stability of Magnet Wire Enamel. Currin, Dexter....227–31; disc. 231
(Basic Sciences) A Method of Solving Mathieu's Equation. Smith....520–5
(Basic Sciences) A Supplement to the Brune Synthesis. Reza....85–90
(Basic Sciences) An Automatic Field Plotter. Gelfand, Shinn, Tuteur....73–8
(Basic Sciences) Analysis of a Triode Oscillator with Losses Associated with the Inductive Branch and Signal Applied in Grid Circuit. Mostafa...777–81
(Basic Sciences) Analysis of Nonlinear Coupled Circuits. Part II. Ku....439–43
(Basic Sciences) Determination of Thermal Life of Enameled Wire by Laboratory Methods. Sattler....70–3
(Basic Sciences) Dielectric Failure of Volume and Surface Types. Chapman, Frisco, Smith....349–54; disc. 354
(Basic Sciences) Effects of Transverse Compressional Stress on Magnetic Laminations. Fischell...190–3
(Basic Sciences) Electric Breakdown of Perfluorocarbon Vapors and Their Mixture With Nitrogen. Berberich, Works, Lindsay....660–5; disc. 665
(Basic Sciences) Equations for the Inductance and Short-Circuit Forces of 3-Phase Busses Comprised of 120-Degree Angles. Maier, Higgins..334–8; disc. 338
(Basic Sciences) Functional Evaluation of Magnetic Wire Insulation. Brancato, Phillips...239–6; disc. 297
(Basic Sciences) Gas and Moisture Equilibriums in Transformer Oil. Kaufman, Shimanski, MacFadyen....312–18; disc. 318
(Basic Sciences) Heat-Resistant Insulation Systems for Motors. Herman, Mathes....561–5
(Basic Sciences) Heat-Resistant Polyester Magnet Wire. Gilliam, Boldebuck, Elliott....557–60
(Basic Sciences) Improving Field Analogues Through Conformal Mapping. Farr, Keen....395–400; disc. 400
(Basic Sciences) Insulation Aging Characteristics as Measured by Shearing Modulus. Whitman, Scheideler....232–8; disc. 238
(Basic Sciences) Junction Transistors Used as Switches. Bright....111–21
(Basic Sciences) Magnetic Flux Density Measurements in Rotating Machines. Ley, Charmatz.....525–8
(Basic Sciences) Phenomena Accompanying Transient Low-Voltage Discharges in Liquid Dielectrics. Williams, Smith....164–9
(Basic Sciences) Properties of Silicon Power Rectifiers. Lusco....106–11
(Basic Sciences) Recommendations of IEC Technical Committee No. 24 on Electric and Magnetic Magnitudes and Units. Smith....37–9
(Basic Sciences) Relation of D-C Magnetic Properties of Oriented 48-Percent Nickel-Iron to Magnetic Amplifier Performance. Ward, Littmann...422–7
(Basic Sciences) Significant Factors in Thermal Aging Tests on Flexible Sheet Insulation. Dakin, Philofsky, Divens....289–92; disc. 292
(Basic Sciences) Some Electrical and Thermal Characteristics of Helium and Sulfur-Hexafluoride Mixtures. Cobine....318–21; disc. 321
(Basic Sciences) Some Properties of Magnetic Fluids. Coolidge, Halberg....149–52
(Basic Sciences) Surface and Volume Dielectric Losses. Chapman, Blickley, Szymkowiak..343–8; disc. 348
(Basic Sciences) Switching Transistors Used as a Substitute for Mechanical Low-Level Choppers. Kruper....141–4
(Basic Sciences) The Dielectric Behavior of Some Fluorogases and Their Mixtures. Camilli, Liao, Plump....637–42; disc. 642
(Basic Sciences) The Propagation Mechanism of Impulse Creepage Discharges Over Oil-Immersed Surfaces. Anderson, Liao....218–26; disc. 226
(Basic Sciences) The Underwater Spark; A Photographic Light Source of High Intrinsic Brilliance. Early, Martin....788–90
(Basic Sciences) Theory of Magnetic Cross-Valves. Higa....204–07; disc. 207
(Basic Sciences) Transfer Functions for Amplitude-Modulated Signals. Hellerman....729–31
(Basic Sciences) What Is a Minimum Phase Network? Balabanian, LePage....785–7; disc. 787
Behavior of Some Fluorogases and Their Mixtures, The Dielectric. Camilli, Liao, Plump.637–42; disc. 642
Bias and Distortion Measuring Instrument, A Portable Telegraph. Cannon....401–06; disc. 406
Bistable Operation, Magnetic Amplifiers in. Finzi, Feth....592–8
Board for Portable Watthour Meter Standards, A New Test. Levitsky....367–70; disc. 370
Breakdown of Perfluorocarbon Vapors and Their Mixture With Nitrogen, Electric. Berberich, Works, Lindsay....660–5; disc. 665
Broad-Band and Pulse Transformer Cores, Presentation of Data on. Gillette, Oshima, Henderson, Rowe....755–63
Brune Synthesis, A Supplement to the. Reza....85–90
Bushings, Progress in the Evaluation of Solid-Core High-Voltage. Brustle, Johnston, Scheideler....387–91; disc. 391
Busses Comprised of 120-Degree Angles, Equations for the Inductance and Short-Circuit Forces of 3-Phase. Maier, Higgins....334–8; disc. 338

C

Cable, A Transatlantic Telephone. Kelly, Radley, Gilman, Halsey....124–36; disc. 136
Cable Carrier and 12-Channel Open-Wire Carrier Systems, Combined Operation of 24-Channel. Searle, Schaefer....770–6; disc. 777
Cables, Shielding of Communication. Gooding, Slade....378–86; disc. 386
Carrier and 12-Channel Open-Wire Carrier Systems, Combined Operation of 24-Channel Cable. Searle, Schaefer....770–6; disc. 777
Carrier Systems, A Pole-Mounted A-C Operated Repeater for 12-Channel Open-Wire. Searle, Schaefer....791–5; disc. 795
Carrier Systems, Frequency-Shift Signaling Circuit for 45-Type. Appert, Caruthers....613–19
Carrier Systems in South Africa, Open-Wire. Boyce....272–81
Carrier Telephone Systems, Aluminum Die Castings for. Pedersen....434–9
Carrier Terminal, A New Audio Telegraph. Higgins, Gilbert....58–62
Cathode Counting Circuits, Cold-. Foote....161–4
Cathode Followers, On the Optimum Design of. Vallese....5–8
Cavity Filters for Multiplexing of 900-Megacycle Radio Relay Systems, Coaxial. Kebby....261–7
Channel Cable Carrier and 12-Channel Open-Wire Carrier Systems, Combined Operation of 24-. Searle, Schaefer....770–6; disc. 777
Characteristics as Measured by Shearing Modulus, Insulation Aging. Whitman, Scheideler....232–8; disc. 238
Characteristics of Helium and Sulfur-Hexafluoride Mixtures, Some Electrical and Thermal. Cobine....318–21; disc. 321
Characteristics of Magnetic Materials, An Accurate Electronic Tracer for Dynamic. Kittl....407–18
Choppers, Switching Transistors Used as a Substitute for Mechanical Low-Level. Kruper....141–4
Circuit, A Multistable Transistor. Henle....568–71
Circuit Design, Notes on the Use of Screen-to-Plate Transconductance in Multigrid Tube. Pullen....648–51; disc. 651

ol. 74

(Computing Devices) Data Transfer and Display Equipment for a Proposed System of Air Traffic Control. Fenimore........145–9
(Computing Devices) Four-Quadrant Multiplication with Transistors and Magnetic Cores. Van Allen........643–7; disc. 647
(Computing Devices) The Design of the IBM Type 702 System. Bashe, Jackson, Mussell, Winger..695–704
Conductor Steel-Reinforced (ACSR) for Railroad Signal and Communications Circuits, Aluminum. Adams........627–9
Configurations for Magnetic Amplifiers Using a Simplified Approach, An Analysis of Optimum Core. Bedford, Willis, Dodson........62–70
Conformal Mapping, Improving Field Analogues Through. Farr, Keen........395–400; disc. 400
Contact Relay, Development of a Wire. Markle..742–5
Contact Type of Schematic Circuit Drawing, An Improved Detached. Meyer........505–13
Continuous-Flow Moisture Detector, A. Beavers, Shimanski, Timpane........361–6; disc. 366
Control of D-C Motors, Magnetic Amplifier. Kusko, Nelson........326–33, disc. 333
Control, Textile Automation by Signal. Casper.176–80
Converter Having an Output Frequency Proportional to the D-C Input Voltage, A Switching Transistor D-C to A-C. Royer........322–4; disc. 324
Converters for Polyphase Power Supplies, Phase Locking of Switching-Transistor. Milnes........587–92
Core Configurations for Magnetic Amplifiers Using a Simplified Approoch, An Analysis of Optimum. Bedford, Willis, Dodson........62–70
Core Materials, Standards for the Presentation of Data on Magnetic Amplifier. (Committee Report).598–9
Core Transformer as a Pickup for Industrial Telemetering Systems, The Movable. Hornfeck, Wermelskirchen........454–62
Cores, Presentation of Data on Broad-Band and Pulse Transformer. Gillette, Oshima, Henderson, Rowe........755–63
Counters in X-Ray Diffraction, Use of Proportional. Laird, Zunick........734–7
Counting Circuits, Cold-Cathode. Foote........161–4
Coupled Circuits, Analysis of Nonlinear. Part II. Ku........439–43
Creepage Discharges Over Oil-Immersed Surfaces, The Propagation Mechanism of Impulse. Anderson, Liao........218–26; disc 226
Cross-Valves, Theory of Magnetic. Higa........204–07; disc. 207
Currents of Double-Way and Double-Wye Rectifiers, Regulator Curves and Transient. Jensen, Rettig........281–7; disc. 287
Curves and Transient Currents of Double-Way and Double-Wye Rectifiers, Regulator. Jensen, Rettig........281–7; disc. 287

D

D-C Dielectric Testing in the Field, The Recognition of Possible Measurement Errors in. Ross, Curdts........630–5; disc. 635
D-C Input Voltage, A Switching Transistor D-C to A-C Converter Having an Output Frequency Proportional to the. Royer........322–4; disc. 324
D-C Magnetic Properties of Oriented 48-Percent Nickel-Iron to Magnetic Amplifier Performance, Relation of. Ward, Littmann........422–7
D-C Motors, Magnetic Amplifier Control of. Kusko, Nelson........326–33; disc. 333
Data from a Poisson Distribution, Machine Testing for Deviation of. Hadden........155–7
Data on Broad-Band and Pulse Transformer Cores, Presentation of. Gillette, Oshima, Henderson, Rowe........755–63
Data on Magnetic Amplifier Core Materials, Standards for the Presentation of. (Committee Report).598–9
Data Transfer and Display Equipment for a Proposed System of Air Traffic Control. Fenimore...145–9
Decicycle Magnetic Amplifier Systems for Servo Applications. Johnson, Rauch........667–72; disc. 672
Delay Device Utilizing Transistors, A High-Accuracy Static Time. Pittman........54–8
Delay-Measuring Instrument in the Audio-Frequency Range, An Envelope. Cannon........710–17
Delays in Gate-Type Operation, The Appraisal of. Molnar........475–85
Demodulator for High-Performance Magnetic Amplifiers in A-C Servo Applications, Transistor. Decker........121–3
Density Measurements in Rotating Machines, Magnetic Flux. Ley, Charmatz........525–8
Design of a Magnetic Frequency Multiplier, Analysis and. Smith, Salihi........99–106
Design of a New 2-Element Single Disk Polyphase Meter, The. Schmidt........513–16
Design of Cathode Followers, On the Optimum. Vallese........5–8
Design of Saturating Reactor Magnetic Pulsers, Economic. Mathias, Williams........169–71
Design of the IBM Type 702 System, The. Bashe, Jackson, Mussell, Winger........695–704
Detached Contact Type of Schematic Circuit Drawing, An Improved. Meyer........505–13
Detector, A Continuous-Flow Moisture. Beavers, Shimanski, Timpane........361–6; disc. 366
Determination of Thermal Life of Enameled Wire by Laboratory Methods. Sattler........70–3
Development of a Wire Contact Relay. Markle...742–5
Developments in Closed-Circuit Television. Kraus........704–09
Device Utilizing Transistors, A High-Accuracy Static Time Delay. Pittman........54–8
Die Castings for Carrier Telephone Systems, Aluminum. Pedersen........434–9
Dielectric Amplifier, Voltage Gain of a Resonant. Sack, Penney........428–34
Dielectric Behavior of Some Fluorogases and Their Mixtures, The. Camilli, Liao, Plump........637–42; disc. 642
Dielectric Failure of Volume and Surface Types. Chapman, Frisco, Smith........349–54; disc. 354
Dielectric Losses, Surface and Volume. Chapman, Blickley, Szymkowiak........343–8; disc. 348
Dielectric Solids, The Effects of High-Energy Gamma Radiation on. Klein, Mannal........723–9
Dielectric Testing in the Field, The Recognition of Possible Measurement Errors in D-C. Ross, Curdts........630–5; disc. 635
Dielectric Tests on a Large Hydrogenerator, Report of. Duke, Ross, Johnson........673–8; disc. 678
Dielectrics, Phenomena Accompanying Transient Low-Voltage Discharges in Liquid. Williams, Smith........164–9
(Dielectrics) The Effect of Reactor Irradiation on Electrical Insulation. Pigg, Bopp, Sisman, Robinson........717–23
Diffraction, Use of Proportional Counters in X-Ray. Laird, Zunick........734–7
Diode Logic Circuits, Engineering Multistage. Yokelson, Ulrich........466–75
Direct-Acting Recording Instruments, A New Line of. Lunas, Nycz........679–84; disc. 684
Discharges in Liquid Dielectrics, Phenomena Accompanying Transient Low-Voltage. Williams, Smith........164–9
Discharges Over Oil-Immersed Surfaces, The Propagation Mechanism of Impulse Creepage. Anderson, Liao........218–26; disc. 226
Disk Type of Tachometer Indicator, Temperature Errors in a Dragmagnet Eddy-Current. Akeley, Fraizer........418–22
Distortion, A Symmetrical Transistor Oscillator with Low Second-Harmonic. Grim...767–70; disc. 770
Distortion Measuring Instrument, A Portable Telegraph Bias and. Cannon........401–06; disc. 406
Distribution, Machine Testing for Deviation of Data from a Poisson. Hadden........155–7
Divider, A Static Magnetic Transistor Analogue. Schaefer........652–5; disc. 655
Division Device, A Novel Circuit for Electronic Power Factor Meters and Wattmeters, and a Novel. Ahmed........194–203; disc. 203
Double-Way and Double-Wye Rectifiers, Regulator Curves and Transient Currents of. Jensen, Rettig........281–7; disc. 287
Dragmagnet Eddy-Current Disk Type of Tachometer Indicator, Temperature Errors in a. Akeley, Fraizer........418–22
Drawing, An Improved Detached Contact Type of Schematic Circuit. Meyer........505–13
Dynamic Characteristics of Magnetic Materials, An Accurate Electronic Tracer for. Kittl......407–18
Dynamic Magnetic Properties of Toroidal Cores, Influence of ID/OD Ratio on Static and. Roberts, Van Nice........599–607

E

Economic Design of Saturating Reactor Magnetic Pulsers. Mathias, Williams........169–71
Eddy-Current Disk Type of Tachometer Indicator, Temperature Errors in a Dragmagnet. Akeley, Fraizer........418–22
Eddy-Current Mutual-Inductance Transducers With High-Conductivity Reference Plates. Joseph, Newman........39–49
Effect of Reactor Irradiation on Electrical Insulation, The. Pigg, Bopp, Sisman, Robinson........717–23
Effects of High-Energy Gamma Radiation on Dielectric Solids. Klein, Mannal........723–9
Effects of Transverse Compressional Stress on Magnetic Laminations. Fischell........190–3
Electric and Magnetic Magnitudes and Units, Recommendations of IEC Technical Committee No. 24 on. Smith........37–9
Electric Breakdown of Perfluorocarbon Vapors and Their Mixture With Nitrogen. Berberich, Works, Lindsay........660–5; disc. 665
Electric System, Operation of a Nuclear Power Plant on an Integrated. Wilson........751–4; disc. 754
Electrical and Thermal Characteristics of Helium and Sulfur-Hexafluoride Mixtures, Some. Cobine........318–21; disc. 321
Electrical Insulation, The Effect of Reactor Irradiation on. Pigg, Bopp, Sisman, Robinson........717–23
Electromotive-Force Transducer and Its Application to Null-Type Recorders, An Angular Position A-C. Guptill, McCarty........610–13
Electronic Circuits, A New Telegraph Serviceboard Using. Davey, Hanley, Purvis........30–7
Electronic Computer for Color Printing. Rose...268–72

Electronic Power Factor Meters and Wattmeters, and a Novel Division Device, A Novel Circuit for. Ahmed ....194–203; disc. 203
Electronic System for Air Traffic Control Information, An. Kalb............152–5
Electronic Tracer for Dynamic Characteristics of Magnetic Materials, An Accurate. Kitil.......407–18
(Electronics) A Symmetrical Transistor Oscillator with Low Second-Harmonic Distortion. Grim............767–70; disc. 770
(Electronics) Cold-Cathode Counting Circuits. Foote 161–4
(Electronics) Machine Testing for Deviation of Data from a Poisson Distribution. Hadden.......155–7
(Electronics) Notes on the Use of Screen-to-Plate Transconductance in Multigrid Tube Circuit Design. Pullen............648–51; disc. 651
(Electronics) On the Equivalent Circuits of Linear Amplifiers. Vallese............691–4
(Electronics) On the Optimum Design of Cathode Followers. Vallese............5–8
(Electronics) Science, Statistics, and Reliability Engineering. Bear............82–5
(Electronics) Shielding of Communication Cables. Gooding, Slade............378–86; disc. 386
Electronics, Ticketfax. Jelinek............565–8.
(Electronics) Use of Proportional Counters in X-Ray Diffraction. Laird, Zunick............734–7.
Electrostatic Potential, Measuring and Recording Atmospheric. Carroll, Hammond, Stewart...517–20
Elimination of Asymmetry Zero-Drift Errors in Magnetic Servo Amplifiers. Geyger.....239–44; disc. 244
Elliptical Polarization Synthesizer, An. Friedman............339–43; disc. 343
Empirical Equations for the 60-Cycle Spark-over Gradients in Commercial Oil. Gauster..301–07; disc. 307
Enamel, A Method for Evaluation of Thermal Stability of Magnet Wire. Currin, Dexter..227–31; disc. 231
Enameled Wire by Laboratory Methods, Determination of Thermal Life of. Sattler............70–3
Energized A-C Windings, A Circuit for Measuring the Resistance of. Seely............214–17; disc. 217
Engineering Multistage Diode Logic Circuits. Yokelson, Ulrich............466–75
Engineering Problems and Performance Record of the Hawaiian Interisland Radio Network. Farinon, Walker............571–6
Engineering, Science, Statistics, and Reliability. Bear 82–5
Envelope Delay-Measuring Instrument in the Audio-Frequency Range, An. Cannon............710–17
Equation, A Method of Solving Mathieu's. Smith 520–5
Equations for the Inductance and Short-Circuit Forces of 3-Phase Busses Comprised of 120-Degree Angles. Maier, Higgins............334–8; disc. 338
Equations for the 60-Cycle Spark-over Gradients in Commercial Oil, Empirical. Gauster............301–07; disc. 307
Equations, Formulation of Magnetic Amplifier Circuit. Schaefer............619–27
Equilibriums in Transformer Oil, Gas and Moisture. Kaufman, Shimanski, MacFadyen............312–18; disc. 318
Equipment for a Proposed System of Air Traffic Control, Data Transfer and Display. Fenimore......145–9
Equipment for Interisland Radio Circuits. Walker, Nolan, Hoover............576–83
Equivalent Circuits of Linear Amplifiers, On the. Vallese............691–4
Errors in a Dragmagnet Eddy-Current Disk Type of Tachometer Indicator, Temperature. Akeley, Fraizer............418–22
Errors in D-C Dielectric Testing in the Field, The Recognition of Possible Measurement. Ross, Curdts............630–5; disc. 635
Errors in Magnetic Servo Amplifiers, Elimination of Asymmetry Zero-Drift. Geyger...239–44; disc. 244
Evaluation of Magnetic Amplifier Response, Oscillographic Techniques for the. Critchlow...607–10
Evaluation of Magnetic Wire Insulation, Functional. Brancato, Phillips............293–6; disc. 297
Evaluation of Solid-Core High-Voltage Bushings, Progress in the. Brustle, Johnston, Scheideler............387–91; disc. 391
Evaluation of Thermal Stability of Magnet Wire Enamel, A Method for. Currin, Dexter..227–31; disc. 231

F

Failure of Volume and Surface Types, Dielectric. Chapman, Frisco, Smith............349–54; disc. 354
Fast Response Magnetic Servo Amplifier, A. Kallander 49–54
Field Analogues Through Conformal Mapping, Improving. Farr, Keen............395–400; disc. 400
Field Plotter, An Automatic. Gelfand, Shinn, Tuteur 73–8
Field Tests on a 100-Megawatt Rectifier Installation. Dillard, Kiefer, Hague............245–52; disc. 252
Film Pickup for Television Broadcasting, Basic Problems in. Gore............462–6
Filters for Multiplexing of 900-Megacycle Radio Relay Systems, Coaxial Cavity. Kebby............261–7
Flexible Sheet Insulation, Significant Factors in Thermal Aging Tests on. Dakin, Philofsky, Divens............289–92; disc. 292
Flow Moisture Detector, A Continuous-. Beavers, Shimanski, Timpane............361–6; disc. 366
Fluids, Some Properties of Magnetic. Coolidge, Halberg 149–52
Fluorogases and Their Mixtures, The Dielectric Behavior of Some. Camilli, Liao, Plump............637–42; disc. 642
Flux Density Measurements in Rotating Machines, Magnetic. Ley, Charmatz............525–8
Force Transducer and Its Application to Null-Type Recorders, An Angular Position A-C Electromotive-. Guptill, McCarty............610–13
Forces of 3-Phase Busses Comprised of 120-Degree Angles, Equations for the Inductance and Short-Circuit. Maier, Higgins.........334–8; disc. 338
Formulation of Magnetic Amplifier Circuit Equations. Schaefer............619–27
Four-Quadrant Multiplication with Transistors and Magnetic Cores. Van Allen......643–7; disc. 647
Frequency Magnetic-Coupled Multivibrator, A Variable. Van Allen............356–61; disc. 361
Frequency Meter, A Transducer-Type. Smith..497–500
FM Receivers, Impulse Noise in Narrow-Band. Lapin, Suran............450–4
Frequency Multiplier, Analysis and Design of a Magnetic. Smith, Salihi............99–106
Frequency Proportional to the D-C Input Voltage, A Switching Transistor D-C to A-C Converter Having an Output. Royer............322–4; disc. 324
Frequency Range, An Envelope Delay-Measuring Instrument in the Audio-. Cannon........710–17
Frequency-Shift Signaling Circuit for 45-Type Carrier Systems. Appert, Caruthers............613–19
Frequency Transistor Power Supply, Operational Magnetic Amplifier with Audio-. Decker, Gourash............490–6
Full-Wave Magnetic Amplifier Output Stage, A New. Barnhart............139–41
Full Wave Reversible Polarity Half Cycle Response Magnetic Amplifiers. House............541–52
Fully Selective Telemetering System Employing Telegraph Facilities, A. Smith, Forrest............373–7; disc. 377
Function Resistor, A Sine. Nielsen, Roland.....447–50
Functional Evaluation of Magnetic Wire Insulation. Brancato, Phillips............293–6; disc. 297
Functions for Amplitude-Modulated Signals, Transfer. Hellerman............729–31

G

Gain of a Resonant Dielectric Amplifier, Voltage. Sack, Penney............428–34
Gamma Radiation on Dielectric Solids, The Effects of High-Energy. Klein, Mannal............723–9
Gas and Moisture Equilibriums in Transformer Oil. Kaufman, Shimanski, MacFadyen............312–18; disc. 318
Gate-Type Operation, The Appraisal of Delays in. Molnar............475–85
Gradients in Commercial Oil, Empirical Equations for the 60-Cycle Spark-over. Gauster............301–07; disc. 307
Grid Circuit, Analysis of a Triode Oscillator with Losses Associated with the Inductive Branch and Signal Applied in. Mostafa............777–81

H

Half Cycle Response Magnetic Amplifiers, Full Wave Reversible Polarity. House............541–52
Harmonic Distortion, A Symmetrical Transistor Oscillator with Low Second-. Grim..767–70; disc. 770
(Hawaiian) Equipment for Interisland Radio Circuits. Walker, Nolan, Hoover............576–83
Hawaiian Interisland Radio Network, Engineering Problems and Performance Record of the. Farinon, Walker............571–6
Hawaiian Telephone Company, The Interisland Radio Network of the. Farinon............529–36
Heat-Resistant Insulation Systems for Motors. Herman, Mathes............561–5
Heat Resistant Polyester Magnet Wire. Gilliam, Boldebuck, Elliott............557–60
Helium and Sulfur-Hexafluoride Mixtures, Some Electrical and Thermal Characteristics of. Cobine ....318–21; disc. 321
Hexafluoride Mixtures, Some Electrical and Thermal Characteristics of Helium and Sulfur-. Cobine ....318–21; disc. 321
High-Accuracy Static Time Delay Device Utilizing Transistors, A. Pittman............54–8
High-Energy Gamma Radiation on Dielectric Solids, The Effects of. Klein, Mannal............723–9
High Frequency Operation of Self-Saturating Magnetic Amplifiers. Collins............500–05
High Frequency Radio Link Between Puerto Rico and the Virgin Islands, Very. McSweeny........781–5
High-Speed Magnetic Amplifier Design, 160,000-Ampere. Rosenstein............90–9
High-Voltage Bushings, Progress in the Evaluation of Solid-Core. Brustle, Johnston, Scheideler............387–91; disc. 391
Hydrogenerator, Report of Dielectric Tests on a Large. Duke, Ross, Johnson............673–8; disc. 678

I

IBM Type 702 System, The Design of the. Bashe, Jackson, Mussell, Winger............695–704
IEC Technical Committee No. 24 on Electric and Magnetic Magnitudes and Units, Recommendations of. Smith............37–9
Impedance and Admittance, Rapid Measurement of. Salzberg, Marini............180–6
Improved Detached Contact Type of Schematic Circuit Drawing, An. Meyer............505–13
Improving Field Analogues Through Conformal Mapping. Farr, Keen............395–400; disc. 400
Impulse Creepage Discharges Over Oil-Immersed Surfaces, The Propagation Mechanism of. Anderson, Liao............218–26; disc. 226
Impulse Noise in Narrow-Band FM Receivers. Lapin, Suran............450–4
Indicator, An Air-borne Temperature. Clark, Amey, Mergner............1–5
Inductance and Short-Circuit Forces of 3-Phase Busses Comprised of 120-Degree Angles, Equations for the. Maier, Higgins............334–8; disc. 338
Inductive Load Instability in Magnetic Amplifiers. Leon, Rosenstein............8–20
Industrial Telemetering Systems, The Movable Core Transformer as a Pickup for. Hornfeck, Wermelskirchen............454–62
Influence of ID/OD Ratio on Static and Dynamic Magnetic Properties of Toroidal Cores. Roberts, Van Nice............599–607
Information, An Electronic System for Air Traffic Control. Kalb............152–5
Input Voltage, A Switching Transistor D–C to A–C Converter Having an Output Frequency Proportional to the D-C. Royer........322–4; disc. 324
Instability in Magnetic Amplifiers, Inductive Load. Leon, Rosenstein............8–20
Instrument, A Portable Telegraph Bias and Distortion Measuring. Cannon............401–06; disc. 406
Instrument in the Audio-Frequency Range, An Envelope Delay-Measuring. Cannon............710–17
Instruments, A New Line of Direct-Acting Recording. Lunas, Nycz............679–84; disc. 684
(Instruments) A New Test Board for Portable Watthour Meter Standards. Levitsky......367–70; disc. 370
(Instruments) A Novel Circuit for Electronic Power Factor Meters and Wattmeters, and a Novel Division Device. Ahmed.........194–203; disc. 203
(Instruments) A Transducer-Type Frequency Meter. Smith............497–500
(Instruments) An Air-borne Temperature Indicator. Clark, Amey, Mergner............1–5
(Instruments) An Elliptical Polarization Synthesizer. Friedman............339–43; disc. 343
(Instruments) Progress in the Evaluation of Solid-Core High-Voltage Bushings. Brustle, Johnston, Scheideler............387–91; disc. 391
(Instruments) Report of Dielectric Tests on a Large Hydrogenerator. Duke, Ross Johnson............673–8; disc. 678
(Instruments) Temperature Errors in a Dragmagnet Eddy-Current Disk Type of Tachometer Indicator. Akeley, Fraizer............418–22
(Instruments) The Design of a New 2-Element Single-Disk Polyphase Meter. Schmidt............513–16
(Instruments) The Movable Core Transformer as a Pickup for Industrial Telemetering Systems. Hornfeck, Wermelskirchen............454–62
(Instruments) The Ring Modulator as a Polarized Rectifier. Hermont............21–30
Insulation Aging Characteristics as Measured by Shearing Modulus. Whitman, Scheideler............232–8; disc. 238
Insulation, Functional Evaluation of Magnetic Wire. Brancato, Phillips............293–6; disc. 297
Insulation, Significant Factors in Thermal Aging Tests on Flexible Sheet. Dakin, Philofsky, Divens............289–92; disc. 292
Insulation Systems for Motors, Heat-Resistant. Herman, Mathes............561–5
Insulation, The Effect of Reactor Irradiation on Electrical. Pigg, Bopp, Sisman, Robinson......717–23
Integrated Electric System, Operation of a Nuclear Power Plant on an. Wilson.......751–4; disc. 754

ol. 74

955

Interference Measurements, A Method of Making Screen Room. Mortenson, Truax.......746–50; disc. 750
Interisland Radio Circuits, Equipment for. Walker, Nolan, Hoover.......576–83
Inter-Island Radio Network of the Hawaiian Telephone Company, The. Farinon.......529–36
Iron to Magnetic Amplifier Performance, Relation of D–C Magnetic Properties of Oriented 48-Percent Nickel-. Ward, Littmann.......422–7
Irradiation on Electrical Insulation, The Effect of Reactor. Pigg, Bopp, Sisman, Robinson.......717–23

J

Junction Transistors Used as Switches. Bright...111–21

L

Laboratory Methods, Determination of Thermal Life of Enameled Wire by. Sattler.......70–3
Laminations, Effects of Transverse Compressional Stress on Magnetic. Fischell.......190–3
Life of Enameled Wire by Laboratory Methods, Determination of Thermal. Sattler.......70–3
Light Source of High Intrinsic Brilliance, The Underwater Spark; A Photographic. Early, Martin.......788–90
Linear Amplifiers, On the Equivalent Circuits of. Vallese.......691–4
Liquid Dielectrics, Phenomena Accompanying Transient Low-Voltage Discharges in. Williams, Smith.......164–9
Load Instability in Magnetic Amplifiers, Inductive. Leon, Rosenstein.......8–20
Locking of Switching-Transistor Converters for Polyphase Power Supplies, Phase. Milnes.......587–92
Logic Circuits, Engineering Multistage Diode. Yokelson, Ulrich.......466–75
Losses Associated with the Inductive Branch and Signal Applied in Grid Circuit, Analysis of a Triode Oscillator with. Mostafa.......777–81
Losses, Surface and Volume Dielectric. Chapman, Blickley, Szymkowiak.......343–8; disc. 348
Low-Level Choppers, Switching Transistors Used as a Substitute for Mechanical. Kruper.......141–4
Low-Voltage Discharges in Liquid Dielectrics, Phenomena Accompanying Transient. Williams, Smith.......164–9

M

Machine Testing for Deviation of Data from a Poisson Distribution. Hadden.......155–7
Magnet Wire Enamel, A Method for Evaluation of Thermal Stability of. Currin, Dexter.......227–31; disc. 231
Magnet Wire, Heat Resistant Polyester. Gilliam, Boldebuck, Elliott.......557–60
Magnetic Amplifier Circuit Equations, Formulation of. Schaefer.......619–27
Magnetic Amplifier Control of D-C Motors. Kusko, Nelson.......326–33; disc. 333
Magnetic Amplifier Core Materials, Standards for the Presentation of Data on. (Committee Report).......598–9
Magnetic Amplifier Design, 160,000-Ampere High Speed. Rosenstein.......90–9
Magnetic Amplifier Output Stage, A New Full-Wave. Barnhart.......139–41
Magnetic Amplifier Response, Oscillographic Techniques for the Evaluation of. Critchlow.......607–10
Magnetic Amplifier Sequential Circuits of the Asymmetrical Type. Fitzgerald.......685–91
Magnetic Amplifier Systems for Servo Applications, Decicycle. Johnson, Rauch.......667–72; disc. 672
Magnetic Amplifier with Audio-Frequency Transistor Power Supply, Operational. Decker, Gourash.......490–6
(Magnetic Amplifiers) A High-Accuracy Static Time Delay Device Utilizing Transistors. Pittman..54–8
(Magnetic Amplifiers) A Switching Transistor D-C to A-C Converter Having an Output Frequency Proportional to the D–C Input Voltage. Royer.......322–4; disc. 324
Magnetic Amplifiers, Full Wave Reversible Polarity Half Cycle Response. House.......541–52
Magnetic Amplifiers, High Frequency Operation of Self-Saturating. Collins.......500–05
Magnetic Amplifiers in A-C Servo Applications, Transistor Demodulator for High Performance. Decker.......121–3
Magnetic Amplifiers in Bistable Operation. Finzi, Feth.......592–8
Magnetic Amplifiers, Inductive Load Instability in. Leon, Rosenstein.......8–20
(Magnetic Amplifiers) Phase Locking of Switching-Transistor Converters for Polyphase Power Supplies. Milnes.......587–92
Magnetic Amplifiers Using a Simplified Approach, An Analysis of Optimum Core Configurations for. Bedford, Willis, Dodson.......62–70
(Magnetic Amplifiers) Voltage Gain of a Resonant Dielectric Amplifier. Sack, Penney.......428–34
Magnetic Audio Amplifier System, An All-. Suozzi, Hooper.......297–300; disc. 300
Magnetic Cores, Four-Quadrant Multiplication with Transistors and. Van Allen.......643–7; disc. 647
Magnetic-Coupled Multivibrator, A Variable Frequency. Van Allen.......356–61; disc. 361
Magnetic Cross-Valves, Theory of. Higa.......204–07; disc. 207
Magnetic Fields, A Survey of Noncontacting Vibration Pickup Using. Clarke.......186–90
Magnetic Fields, The Application of Perpendicularly Superposed. Heartz, Buelteman..655–9; disc. 659
Magnetic Fluids, Some Properties of. Coolidge, Halberg.......149–52
Magnetic Flux Density Measurements in Rotating Machines. Ley, Charmatz.......525–8
Magnetic Frequency Multiplier, Analysis and Design of a. Smith, Salihi.......99–106
Magnetic Laminations, Effects of Transverse Compressional Stress on. Fischell.......190–3
Magnetic Magnitudes and Units, Recommendations of IEC Technical Committee No. 24 on Electric and. Smith.......37–9
Magnetic Materials, An Accurate Electronic Tracer for Dynamic Characteristics of. Kittl.......407–18
Magnetic Properties of Oriented 48-Percent Nickel-Iron to Magnetic Amplifier Performance, Relation of D-C. Ward, Littmann.......422–7
Magnetic Properties of Toroidal Cores, Influence of ID/OD Ratio on Static and Dynamic. Roberts, Van Nice.......599–607
Magnetic Pulsers, Economic Design of Saturating Reactor. Mathias, Williams.......169–71
Magnetic Servo Amplifier, A Fast Response. Kallander.......49–54
Magnetic Servo Amplifiers, Elimination of Asymmetry Zero-Drift Errors in. Geyger.......239–44; disc. 244
Magnetic Transistor Analogue Divider, A Static. Schaefer.......652–5; disc. 655
Magnetic Wire Insulation, Functional Evaluation of. Brancato, Phillips.......293–6; disc. 297
Magnitudes and Units, Recommendations of IEC Technical Committee No. 24 on Electric and Magnetic. Smith.......37–9
Mapping, Improving Field Analogues Through Conformal. Farr, Keen.......395–400; disc. 400
Mapping Sequential Circuits, Minimizing and. Bennett.......443–7
Materials, Standards for the Presentation of Data on Magnetic Amplifier Core. (Committee Report).......598–9
Mathieu's Equation, A Method of Solving. Smith.......520–5
Measurement Errors in D-C Dielectric Testing in the Field, The Recognition of Possible. Ross, Curdts.......630–5; disc. 635
Measurement of Impedance and Admittance, Rapid. Salzberg, Marini.......180–6
Measurement of Small Torques, A Precision Torque Balance for the. Matthys.......485–90
Measurements, A Method of Making Screen Room Interference. Mortenson, Truax.......746–50; disc. 750
(Measurements) An Angular Position A-C Electromotive-Force Transducer and Its Application to Null-Type Recorders. Guptill, McCarty...610–13
(Measurements) Eddy-Current Mutual-Inductance Tranducers with High-Conductivity Reference Plates. Joseph, Newman.......39–49
Measurements in Rotating Machines, Magnetic Flux Density. Ley, Charmatz.......525–8
Measuring and Recording Atmospheric Electrostatic Potential. Carroll, Hammond, Stewart....517–20
Measuring Instrument, A Portable Telegraph Bias and Distortion. Cannon.......401–06; disc. 406
Measuring Instrument in the Audio-Frequency Range, An Envelope Delay-. Cannon.......710–17
Measuring the Resistance of Energized A-C Windings, A Circuit for. Seely.......214–17; disc. 217
Mechanical Low-Level Choppers, Switching Transistors Used as a Substitute for. Kruper.......141–4
Mechanism of Impulse Creepage Discharges Over Oil-Immersed Surfaces, The Propagation. Anderson, Liao.......218–26; disc. 226

Radio System, The Seattle-Victoria. Kistler....737–41
Railroad Signal and Communications Circuits, Aluminum Conductor Steel-Reinforced (ACSR) for. Adams.......................................627–9
Rapid Measurement of Impedance and Admittance. Salzberg, Marini...........................180–6
Ratio on Static and Dynamic Magnetic Properties of Toroidal Cores, Influence of ID/OD. Roberts, Van Nice.......................................599–607
Reactor Irradiation on Electrical Insulation, The Effect of. Figg, Bopp, Sisman, Robinson...717–23
Reactor Magnetic Pulsers, Economic Design of Saturating. Mathias, Williams...................169–71
Receiver Signal Overload, Television. Masucci...78–82
Receivers, Impulse Noise in Narrow-Band FM. Lapin, Suran.......................................450–4
Recognition of Possible Measurement Errors in D-C Dielectric Testing in the Field, The. Ross, Curdts.......................................630–5; disc. 635
Recommendations of IEC Technical Committee No. 24 on Electric and Magnetic Magnitudes and Units. Smith.......................................37–9
Recorders, An Angular Position A-C Electromotive-Force Transducer and Its Application to Null-Type. Guptill, McCarty................610–13
Recorders, Ticketfax Transmitters and. Zabriskie.......................................536–41
Recording Atmospheric Electrostatic Potential, Measuring and. Carroll, Hammond, Stewart.....517–20
Recording Instruments, A New Line of Direct-Acting. Lunas, Nyez..............679–84; disc. 684
Rectifier Installation, Field Tests on a 100-Megawatt. Dillard, Kiefer, Hague..........245–52; disc. 252
Rectifier, The Ring Modulator as a Polarized. Hermont.......................................21–30
Rectifiers for High Temperature Operation, Selenium. Isaacson.......................................552–7
Rectifiers, Properties of Silicon Power. Losco...106–11
Rectifiers, Regulator Curves and Transient Currents of Double-Way and Double-Wye. Jensen, Rettig.......................................281–7; disc. 287
Reference Plates, Eddy-Current Mutual-Inductance Transducers with High-Conductivity. Joseph, Newman.......................................39–49
Regulator Curves and Transient Currents of Double-Way and Double-Wye Rectifiers. Jensen, Rettig.......................................281–7; disc. 287
Relation of D-C Magnetic Properties of Oriented 48-Percent Nickel-Iron to Magnetic Amplifier Performance. Ward, Littmann...............422–7
Relay, Development of a Wire Contact. Markle...742–5
Relay Systems, Coaxial Cavity Filters for Multiplexing of 900-Megacycle Radio. Kebby..........261–7
Relay Using Momentum Transfer, A Polar. Garbarino, Bisshopp.............................731–3
Reliability Engineering, Science, Statistics and. Bear.......................................82–5
Repeater for 12-Channel Open-Wire Carrier Systems, A Pole-Mounted A-C Operated. Searle, Schaefer.......................................791–5; disc. 795
Report of Dielectric Tests on a Large Hydrogenerator. Duke, Ross, Johnson..............673–8; disc. 678
Resistance of Energized A-C Windings, A Circuit for Measuring the. Seely..........214–17; disc. 217
Resistor, A Sine Function. Nielsen, Roland.....447–50
Resonant Dielectric Amplifier, Voltage Gain of a. Sack, Penney...............................428–34
Response Magnetic Amplifiers, Full Wave Reversible Polarity Half Cycle. House..................541–52
Response, Oscillographic Techniques for the Evaluation of Magnetic Amplifier. Critchlow.........607–10
Ring Modulator as a Polarized Rectifier, The. Hermont.......................................21–30
Roll-Welding Precious Metals for Telephone Contacts. Quinlan.......................................763–6
Rotating Machines, Magnetic Flux Density Measurements in. Ley, Charmats...................525–8
Rural Subscriber Service, Telephone Lines for. Hochgraf, Watling............................171–6

S

Saturating Reactor Magnetic Pulsers, Economic Design of. Mathias, Williams...................169–71
Schematic Circuit Drawing, An Improved Detached Contact Type of. Meyer...................505–13
Science, Statistics, and Reliability Engineering. Bear.......................................82–5
Screen Room Interference Measurements, A Method of Making. Mortenson, Truax....746–50; disc. 750
Screen-to-Plate Transconductance in Multigrid Tube Circuit Design, Notes on the Use of. Pullen.......................................648–51; disc. 651
Seattle-Victoria Radio System, The. Kistler....737–41
Second-Harmonic Distortion, A Symmetrical Transistor Oscillator with Low. Grim.....767–70; disc. 770
Selenium Rectifiers for High Temperature Operation. Isaacson.......................................552–7
Self-Saturating Magnetic Amplifiers, High-Frequency Operation of. Collins...................500–05
Sequential Circuits, Minimizing and Mapping. Bennett.......................................443–7; disc. 796
Sequential Circuits of the Asymmetrical Type, Magnetic Amplifier. Fitzgerald...................685–91
Service, Telephone Lines for Rural Subscriber. Hochgraf, Watling............................171–6
Serviceboard Using Electronic Circuits, A New Telegraph. Davey, Hanley, Purvis.................30–7
Servo Amplifier, A Fast Response Magnetic. Kallander.......................................49–54
Servo Amplifiers, Elimination of Asymmetry Zero-Drift Errors in Magnetic. Geyger.......................................239–44; disc. 244
Servo Applications, Decicycle Magnetic Amplifier Systems for. Johnson, Rauch....667–72; disc. 672
Servo Applications, Transistor Demodulator for High Performance Magnetic Amplifiers in A-C. Decker.......................................121–3
Shearing Modulus, Insulation Aging Characteristics as Measured by. Whitman, Scheideler.......................................232–8; disc. 238
Sheet Insulation, Significant Factors in Thermal Aging Tests on Flexible. Dakin, Philofsky, Divens.......................................289–92; disc. 292
Shielding of Communication Cables. Gooding, Slade.......................................378–86; disc. 386
Shift Signaling Circuit for 45-Type Carrier Systems, Frequency-. Appert, Caruthers............613–19
Short-Circuit Forces of 3-Phase Busses Comprised of 120-Degree Angles, Equations for the Inductance and. Maier, Higgins..................334–8; disc. 338
Signal and Communications Circuits, Aluminum Conductor Steel-Reinforced (ACSR) for Railroad. Adams.......................................627–9
Signal Control, Textile Automation by. Casper.......................................176–80
Signal Overload, Television Receiver. Masucci...78–82

Signaling Circuit for 45-Type Carrier Systems, Frequency-Shift. Appert, Caruthers.........613–19
Signals, Transfer Functions for Amplitude-Modulated. Hellerman.........729–31
Significant Factors in Thermal Aging Tests on Flexible Sheet Insulation. Dakin, Philofsky, Divens.........289–92; disc. 292
Silicon Power Rectifiers, Properties of. Losco...106–11
Sine Function Resistor, A. Nielsen, Roland.....447–50
Single Disk Polyphase Meter, The Design of a New 2-Element. Schmidt.........513–16
60-Cycle Spark-over Gradients in Commercial Oil, Empirical Equations for the. Gauster.........301–07; disc. 307
Solid-Core High-Voltage Bushings, Progress in the Evaluation of. Brustle, Johnston, Scheideler.........387–91; disc. 391
Solids, The Effects of High-Energy Gamma Radiation on Dielectric. Klein, Mannal.........723–9
Some Electrical and Thermal Characteristics of Helium and Sulfur-Hexafluoride Mixtures. Cobine.........318–21; disc. 321
Some Properties of Magnetic Fluids. Coolidge, Halberg.........149–52
South Africa, Open-Wire Carrier Systems in. Boyce.........272–81
Spark; A Photographic Light Source of High Intrinsic Brilliance, The Underwater. Early, Martin.........788–90
Spark-over Gradients in Commercial Oil, Empirical Equations for the 60-Cycle. Gauster.........301–07; disc. 307
Stability of Magnet Wire Enamel, A Method for Evaluation of Thermal. Currin, Dexter.........227–31; disc. 231
Stage, A New Full-Wave Magnetic Amplifier Output. Barnhart.........139–41
Standards, A New Test Board for Portable Watthour Meter. Levitsky.........367–70; disc. 370
Standards for the Presentation of Data on Magnetic Amplifier Core Materials. (Committee Report).........598–9
Static and Dynamic Magnetic Properties of Toroidal Cores, Influence of ID/OD Ratio on. Roberts, Van Nice.........599–607
Static Magnetic Transistor Analogue Divider, A. Schaefer.........652–5; disc. 655
Static Time Delay Device Utilizing Transistors, A High Accuracy. Pittman.........54–8
Statistics and Reliability Engineering, Science. Bear.........82–5
Steel-Reinforced (ACSR) for Railroad Signal and Communications Circuits, Aluminum Conductor. Adams.........627–9
Stress on Magnetic Laminations, Effects of Transverse Compressional. Fischell.........190–3
Subscriber Service, Telephone Lines for Rural. Hochgraf, Watling.........171–6
Substitute for Mechanical Low-Level Choppers, Switching Transistors Used as a. Kruper.........141–4
Sulfur-Hexafluoride Mixtures, Some Electrical and Thermal Characteristics of Helium and. Cobine.........318–21; disc. 321
Superposed Magnetic Fields, The Application of Perpendicularly. Heartz, Buelteman.........655–9; disc. 659
Supplement to the Brune Synthesis, A. Reza....85–90
Surface and Volume Dielectric Losses. Chapman, Blickley, Szymkowiak.........343–8; disc. 348
Surface Types, Dielectric Failure of Volume and. Chapman, Frisco, Smith.........349–54; disc. 354
Survey of Noncontacting Vibration Pickup Using Magnetic Fields, A. Clarke.........186–90
Switches, Junction Transistors Used as. Bright...111–21
Switching-Transistor Converters for Polyphase Power Supplies, Phase Locking of. Milnes.........587–92
Switching Transistor D-C to A-C Converter Having an Output Frequency Proportional to the D-C Input Voltage, A. Royer.........322–4; disc. 324
Switching Transistors Used as a Substitute for Mechanical Low-Level Choppers. Kruper.....141–4
Symmetrical Transistor Oscillator with Low Second-Harmonic Distortion, A. Grim...767–70; disc. 770
Synthesis, A Supplement to the Brune. Reza....85–90
Synthesizer, An Elliptical Polarization. Friedman.........339–43; disc. 343
System, The Ticketfax. Hill.........583–6

T

Tachometer Indicator, Temperature Errors in a Dragmagnet Eddy-Current Disk Type of. Akeley, Fraizer.........418–22
Tapered Strip Transmission Line for Pulse Transformer Service, A. Primozich, Schatz, Woodford..158–61
(Telegraph) A Polar Relay Using Momentum Transfer. Garbarino, Bisshopp.........731–3
(Telegraph) An Envelope Delay-Measuring Instrument in the Audio-Frequency Range. Cannon...710–17
Telegraph Bias and Distortion Measuring Instrument, A Portable. Cannon.........401–06; disc. 406
Telegraph Carrier Terminal, A New Audio. Higgins, Gilbert.........58–62
Telegraph Facilities, A Fully Selective Telemetering System Employing. Smith, Forrest.........373–7; disc. 377
Telegraph Serviceboard Using Electronic Circuits, A New. Davey, Hanley, Purvis.........30–7
(Telegraph Systems) Textile Automation by Signal Control. Casper.........176–80
(Telegraph Systems) The Ticketfax System. Hill.........583–6
(Telegraph Systems) Ticketfax Electronics. Jelinek.........565–8
(Telegraph Systems) Ticketfax Transmitters and Records. Zabriskie.........536–41
Telemetering System Employing Telegraph Facilities, A Fully Selective. Smith, Forrest...373–7; disc. 377
Telemetering Systems, The Movable Core Transformer as a Pickup for Industrial. Hornfeck, Wermelskirchen.........454–62
Telephone Cable, A Transatlantic. Kelly, Radley, Gilman, Halsey.........124–36; disc. 136
Telephone Contacts, Roll-Welding Precious Metals for. Quinlan.........763–6
Telephone Lines for Rural Subscriber Service. Hochgraf, Watling.........171–6
Telephone Systems, Aluminum Die Castings for Carrier. Pedersen.........434–9
(Telephone) The Appraisal of Delays in Gate-Type Operation. Molnar.........475–85
Television Broadcasting, Basic Problems in Film Pickup for. Gore.........462–6
Television, Developments in Closed-Circuit. Kraus.........704–09
Television Receiver Signal Overload. Masucci...78–82
Temperature Errors in a Dragmagnet Eddy-Current Disk Type of Tachometer Indicator. Akeley, Fraizer.........418–22
Temperature Indicator, An Air-borne. Clark, Amey, Mergner.........1–5
Temperature Operation, Selenium Rectifiers for High. Isaacson.........552–7
Terminal, A New Audio Telegraph Carrier. Higgins, Gilbert.........58–62
Test Board for Portable Watthour Meter Standards, A New. Levitsky.........367–70; disc. 370
Testing for Deviation of Data from a Poisson Distribution, Machine. Hadden.........155–7
Testing in the Field, The Recognition of Possible Measurement Errors in D-C Dielectric. Ross, Curdts.........630–5; disc. 635
Tests on a Large Hydrogenerator, Report of Dielectric. Duke, Ross, Johnson.........637–8; disc. 678
Tests on a 100-Megawatt Rectifier Installation, Field. Dillard, Kiefer, Hague.........245–52; disc. 252
Textile Automation by Signal Control. Casper.........176–80
Theory of Magnetic Cross-Valves. Higa.........204–07; disc. 207
Thermal Aging Tests on Flexible Sheet Insulation, Significant Factors in. Dakin, Philofsky, Divens.........289–92; disc. 292
Thermal Characteristics of Helium and Sulfur-Hexafluoride Mixtures, Some Electrical and. Cobine.........318–21; disc. 321
Thermal Life of Enameled Wire by Laboratory Methods, Determination of. Sattler.........70–3
Thermal Stability of Magnet Wire Enamel, A Method for Evaluation of. Currin, Dexter.........227–31; disc. 231
Three-Phase Busses Comprised of 120-Degree Angles, Equations for the Inductance and Short-Circuit Forces of. Maier, Higgins.........334–8; disc. 338
Ticketfax Electronics. Jelinek.........565–8
Ticketfax System, The. Hill.........583–6
Ticketfax Transmitters and Recorders. Zabriskie.........536–41
Time Delay Device Utilizing Transistors, A High-Accuracy Static. Pittman.........54–8
Toroidal Cores, Influence of ID/OD Ratio on Static and Dynamic Magnetic Properties of. Roberts, Van Nice.........599–607
Torque Balance for the Measurement of Small Torques, A Precision. Matthys.........485–90
Tracer for Dynamic Characteristics of Magnetic Materials, An Accurate Electronic. Kittl.....407–18
Traffic Control, Data Transfer and Display Equipment for a Proposed System of Air. Fenimore.....145–9
Traffic Control Information, An Electronic System for Air. Kalb.........152–5
Transatlantic Telephone Cable, A. Kelly, Radley, Gilman, Halsey.........124–36; disc. 136
Transconductance in Multigrid Tube Circuit Design, Notes on the Use of Screen-to-Plate. Pullen.........648–51; disc. 651
Transducer and Its Application to Null-Type Recorders, An Angular Position A-C Electromotive-Force. Guptill, McCarty.........610–13
Transducer-Type Frequency Meter, A. Smith.........497–500
Transducers with High-Conductivity Reference Plates, Eddy-Current Mutual-Inductance. Joseph, Newman.........39–49
Transfer, A Polar Relay Using Momentum. Garbarino, Bisshopp.........731–3
Transfer Functions for Amplitude-Modulated Signals. Hellerman.........729–31
Transformer as a Pickup for Industrial Telemetering Systems, The Movable Core. Hornfeck, Wermelskirchen.........454–62
Transformer Cores, Presentation of Data on Broad-Band and Pulse. Gillette, Oshima, Henderson, Rowe.........755–63
Transformer Oil, Gas and Moisture Equilibriums in. Kaufman, Shimanski, MacFadyen.........312–18; disc. 318
Transformer Service, A Tapered Strip Transmission Line for Pulse. Primozich, Schatz, Woodford...158–61
Transient Currents of Double-Way and Double-Wye Rectifiers, Regulator Curves and. Jensen, Rettig.........281–7; disc. 287
Transient Low-Voltage Discharges in Liquid Dielectrics, Phenomena Accompanying. Williams, Smith.........164–9
Transistor Analogue Divider, A Static Magnetic. Schaefer.........562–5; disc. 655
Transistor Circuit, A Multistable. Henle......568–71
Transistor Converters for Polyphase Power Supplies, Phase Locking of Switching-. Milnes......587–92
Transistor D-C to A-C Converter Having an Output Frequency Proportional to the D-C Input Voltage, A Switching. Royer.........322–4; disc. 324
Transistor Demodulator for High Performance Magnetic Amplifiers in A-C Servo Applications. Decker.........121–3
Transistor Oscillator with Low Second-Harmonic Distortion, A Symmetrical. Grim...767–70; disc. 770
Transistor Power Supply, Operational Magnetic Amplifier with Audio-Frequency. Decker, Gourash.........490–6
Transistors, A High-Accuracy Static Time Delay Device Utilizing. Pittman.........54–8
Transistors and Magnetic Cores, Four-Quadrant Multiplication with. Van Allen.......643–7; disc. 647
Transistors Used as a Substitute for Mechanical Low-Level Choppers, Switching. Kruper.......141–4
Transistors Used as Switches, Junction. Bright..111–21
Transmission Line for Pulse Transformer Service, A Tapered Strip. Primozich, Schatz, Woodford.........158–61
Transmitters and Recorders, Ticketfax. Zabriskie.........536–41
Transverse Compressional Stress on Magnetic Laminations, Effects of. Fischell.........190–3
Triode Oscillator with Losses Associated with the Inductive Branch and Signal Applied in Grid Circuit, Analysis of a. Mostafa.........777–81
Tube Circuit Design, Notes on the Use of Screen-to-Plate Transconductance in Multigrid. Pullen.........648–51; disc. 651
12-Channel Open-Wire Carrier Systems, A Pole-Mounted A-C Operated Repeater for. Searle, Schaefer.........791–5; disc. 795
24-Channel Cable Carrier and 12-Channel Open-Wire Carrier Systems, Combined Operation of. Searle, Schaefer.........770–6; disc. 777
Two-Element Single Disk Polyphase Meter, The Design of a New. Schmidt.........513–16

An Air-borne Temperature Indicator

W. R. CLARK

W. G. AMEY
MEMBER AIEE

G. C. MERGNER
ASSOCIATE MEMBER AIEE

THIS paper describes an air-borne temperature indicator which was developed specifically for the U. S. Army Signal Corps, Belmar, N. J. While the specification indicated that the instrument should be of the electromechanical null-balance type,[1] many of the required features represented significant departures from those of somewhat similar instruments used in industrial applications. Operation from a 115-volt (±10 per cent) 400-cycle (±5 per cent) power source was required, and the instrument was to have a range of −70 to +60 degrees centigrade (C) (4.92 millivolts for a copper-constantan thermocouple). The full-scale response time was specified to be less than 10 seconds, the minimum sensitivity 4 microvolts (0.14 C), and the limit of error ±1 C. Operation in accordance with these specifications, as well as storage without power connected, over an ambient temperature range of −55 to +55 C was required; this requirement precluded the use of dry batteries or standard cells. The indicator had to be small in size and weight, be sufficiently rugged to withstand severe shock and vibration, and develop sufficient torque to position a synchro transmitter.

These specifications indicated that there were two principal problems to be solved:

1. The development of a compact, lightweight, electromechanical balancing system which would have the required sensitivity, torque, response time, and freedom from adverse effects caused by shock or vibration.

2. The development of a new potentiometric system which would ensure the desired accuracy over the entire range of ambient temperature without employing batteries or standard cells.

General Description

The instrument developed meets the foregoing specifications. It is housed in a welded aluminum case designed for panel mounting and gasketed to be dust-proof. The main scale indications can be seen through a window, as shown in Fig. 1. The circular scale is marked with fluorescent paint in 1-degree divisions from −70 to +60 C. All controls necessary to the normal operation of the indicator and connectors for external circuits are mounted on the aluminum front panel which is rigidly attached to the aluminum main frame. This assembly slides in and out of the case as shown in Fig. 2. On the frame are mounted the balancing motor and synchro transmitter. On the back of the frame, Fig. 3, are mounted components associated with the potentiometer circuit and its current supply: measuring slide wire with its associated resistance coils and rheostats, compensating coils, voltage reference tubes, and thermostat. The balancing amplifier and the electronic portion of the regulated potentiometer current supply are mounted on an aluminum chassis, Fig. 4, connections to which are made through a multipin connector.

Balancing System

The balancing system, shown schematically in Fig. 5, is similar in principle to that used in the present-day Leeds & Northrup type-*G* recorders, except that the synchronous converter, balancing amplifier, and motor had to be specially designed to operate from a 400-cycle power source. A special 400-cycle synchronous converter was developed to meet the stringent requirements of this application. Tests of commercially available converters indicated insufficient long-term stability, excessive pickup from the drive coil, excessive contact noise, and susceptibility to ambient temperature changes. Operation of the new converter is independent of normal line voltage or line frequency changes. The drive coil requires 2.4 watts at 40 volts. Magnetic and electrostatic pickup in the low-level circuit of the converter is negligible at the operating level of the indicator. The converter does not introduce any appreciable noise into the amplifier and does not produce any significant zero offset of the indicator.

The balancing amplifier must have a sensitivity of approximately 4 microvolts (0.14 C). The unusually wide range of ambient temperature requires special precautions throughout the entire low-level circuit in order to prevent generation of voltages from thermal causes. The single-section resistance-capacitance filter used in the input circuit attenuates pickup in the thermocouple leads and ensures proper damping of the indicator without oscillation. The capacitor developed specially for this filter is relatively free from self-generated spurious currents over the entire range of ambient temperature. The synchronous converter converts any difference between the potentiometer voltage and the thermocouple voltage to a 400-cycle voltage which is stepped up by the input transformer and amplified by a 4-stage voltage amplifier (one *12AY7* twin triode and one *12AX7* twin triode). This part of the amplifier is enclosed in a shielded compartment. All leads enter via feed-through capacitors which filter out external, transient, high-frequency disturbances. The last stage of the voltage amplifier drives a single tube *6AQ5* power output stage which in turn drives the balancing motor. This tube supplies 3 watts at 400 cycles to the motor. A single rectifier tube supplies the direct-current voltage for both the amplifier and the regulated potentiometer supply. Because of the wide range of ambient temperatures no electrolytic capacitors are used in the indicator.

All heaters are operated from alternating current, but the input tube must be of a type which is inherently free from noise and hum. The level at which this tube operates requires using a special shielded socket to shield the grid and plate pins from the alternating current of the heater leads.

The motor is a 2-phase unit which delivers a maximum torque of 1 ounce-inch. It has a built-in gear reduction of

30 to 1 and a single external reduction of 16 to 1 to couple the motor to the slide-wire shaft. This final reduction employs antibacklash gearing to reduce the indicator deadband to a negligible amount. The slide wire shaft drives the contact arm of the measuring slide wire, the main calibrated scale, and the gearing for coupling to the synchro transmitter. One phase of the motor is energized from the line through a capacitor and the other phase is energized by the amplifier.

Potentiometric System

The major part of the air-borne temperature indicator problem was the development of a good substitute for the dry battery and standard cell. The *5651* voltage reference tube seemed to offer good possibilities of providing this substitute. An exhaustive experimental investigation of its characteristics indicated that:

1. Its voltage regulation characteristic remained quite constant for long periods of time.
2. It had no discontinuities of regulation as did the voltage regulator tubes.
3. Exposure to extreme temperatures did not damage the tube nor permanently change its voltage-current characteristic.
4. While its voltage-current characteristic was displaced with temperature, the shape of the curve remained practically constant, as shown in Fig. 6.
5. The shape of the curve was found to be quite reproducible from tube to tube.

These results led to the conclusion that the *5651* tube could be used in much the same manner as a standard cell if proper temperature compensation were provided or if the *5651* tube were always operated at a constant temperature independent of outside temperature variation.

Since the temperature coefficient of voltage of the *5651* is small, approximately −0.0033 per cent per C, and since it is fairly constant over a considerable range of temperature (Fig. 7), compensation can be accomplished by the use of a series resistor of copper which has a linear positive coefficient. The resultant calculated voltage variation is very small, and experimental results check the calculated curve. Since the resistance of the copper resistor is small, it does not appreciably affect the performance of the *5651* tube.

To ensure close "tracking" as the temperature varies, the *5651* tube must be located close to its compensating resistor and must be thermally "lagged" to match the slower response of the resistor. For reasons discussed later, the potentiometer circuit compartment is thermostatically controlled so that its operating temperature never gets below −30 C. Therefore, close compensation of the *5651* tube below this temperature is not important.

Operated under these conditions, the *5651* tube with its compensating resistor became the basic element of the potentiometric system, of which there are two main parts:

1. A well-regulated d-c power supply, shown schematically in Fig. 8.
2. The potentiometer circuit, shown schematically in Fig. 9.

REGULATED D-C POWER SUPPLY

The direct current for this supply is obtained from the same rectified supply as the direct current used for the balancing system amplifier. Fundamentally, in order to obtain a regulated d-c supply, all that is necessary is to maintain the adjustment of a rheostat placed in series with the unregulated d-c supply so that the voltage across the load remains constant independent of line voltage variations.[2] The method used to accomplish this is shown in Fig. 8. It employs a single tube (*12AX7*) differential-type d-c control amplifier for comparing a direct voltage from the voltage reference tube *5651* with a direct voltage which varies when the a-c line voltage varies. The output

of this stage is amplified by a pentode tube *6AU6* and this amplified output is used to control the resistance of the rheostat tube *6AQ5*.

The output from the rheostat tube, Fig. 8, supplies the direct voltage which is compared with a portion of the reference tube voltage by the *12AX7* tube. It also supplies the current for the parallel combination of the voltage reference tube just mentioned and the load, through a common adjustable series resistance. This series resistance is considerably higher in value than the equivalent resistance of the voltage reference tube-load combination, thus permitting the voltage reference tube to act as a voltage regulator tube and provide a second stage of regulation.

In this application the load remains constant at 10 milliamperes and the voltage reference tube current is 2.5 milliamperes. A change in line voltage of ±10 per cent produces a change in voltage across the *5651* tube of less than ±0.05 per cent. The temperature compensation provided is sufficient to limit the error resulting from changes in ambient temperature of −55 to +55 C to ±0.04 per cent.

The d-c supply used for the balancing system amplifier is connected to the case which is normally grounded. For simplicity, this supply is also used as the source of the potentiometer current. This limits the system to use with ungrounded thermocouples.

POTENTIOMETER CIRCUIT

The potentiometer circuit is shown in Fig. 9. Some of the functions of some parts of the circuit have already been described, i.e., the series resistor (STD ADJ) and the voltage reference tube (*5651* NORM) with its compensating resistor (COMP COIL). The circuit referred to previously as the load consists of an adjustable resistance *F* in series with a 2-branch measuring circuit. A reference junction compensating coil *D* in one branch of the measuring circuit permits a direct indication of temperature.[3] This type of compensation has been widely used in numerous industrial instruments for normal ranges of ambient temperatures. The temperature of the potentiometer circuit compartment of the indicator is thermostatically controlled (mentioned previously) primarily to reduce the range of temperature over which compensation is required. Except for two minor features this measuring circuit is identical to those used in the potentiometer-type Speedomax temperature recorders commonly used in industry. The exceptions are:

1. Use of a continuous-type slide wire in place of the more common wound-type slide wire.
2. The addition, to the slide-wire branch of the circuit, of a coil *D'* which has the same resistance and temperature coefficient as the reference junction coil *D*.

The continuous slide wire *S* is used to achieve better damping and more usable sensitivity than can be obtained with the wound-type slide wire.

The *D'* coil maintains the equality of both branches of the potentiometer circuit. This precaution is unnecessary in industrial instruments, where, under normal operating conditions, the change in the resistance of *D* is negligible compared to the total resistance in each measuring

circuit branch. The extremely wide range of ambient temperature and the specified low limit of error required for this indicator make this refinement essential as it ensures equal currents in each branch of the measuring circuit at all operating temperatures. Since the change in total resistance of the measuring circuit caused by the variation of resistances D and D' with temperature is negligible compared to the series resistance F, the current to the measuring circuit remains practically constant. The junction of the constantan thermocouple lead and the copper lead of the measuring circuit is insulated from but fastened to the reference junction coil D to maintain these two components at the same temperature, thus providing for good reference junction compensation.

The system described thus far will maintain a constant current through the potentiometer and, if this current is of the correct value, accurate indicator readings can be obtained over the entire range of ambient temperature. A method of obtaining this correct value will be described next.

For a given value of F the total current through the measuring circuit is governed by the voltage at which the *5651* tube operates. This voltage is not the same for every tube, but if a definite operating current is selected for the *5651* tube, then every tube can be calibrated in terms of the value of F required to ensure a total measuring circuit current of 10 milliamperes. With the rheostat set at its correct value for the particular *5651* tube in use, the current through the measuring circuit can be standardized.

In series with the copper resistor in the *5651* branch is a small resistor E of Evanohm (2.652 ohms). When the STD-TC switch on the front panel is held in the STD position, the self-balancing action of the indicator may be used to compare the voltage across E to the voltage drop from the slide-wire contact to P. A scale reading of O indicates the establishment of the desired current values, 2.5 milliamperes in the *5651* branch and 5.0 milliamperes through the slide wire. Because the voltage across a given type-*5651* tube is relatively constant, despite small variations of the current through it, the desired balance obtains for one, and only one, value of voltage across the parallel measuring and *5651* circuits (M to P). As that voltage is varied from the balance value by the STD ADJ rheostat, the current through the *5651* tube varies percentagewise at a rate approximately 25 times that of the current in the measuring circuit. Therefore, for an indicator limit of error of 0.1 per cent of range (5 microvolts), the current need be adjusted only to a point where the indicator reading is within 125 microvolts, or about three scale divisions, of scale 0 during the standardization procedure. Thus the voltage reference tube not only provides the reference voltage for the regulated supply but also furnishes the standard voltage for standardizing the potentiometer circuit.

While tests showed that the *5651* tubes held their calibration for quite a long time, it was considered desirable to provide some convenient method of making a quick check of this standard voltage. For this purpose a second *5651* tube (CHECK) and its associated rheostat F' are supplied. This rheostat is, of course, set to the correct value for the CHECK *5651* tube. If a constant input signal is applied to the indicator, the stability of the calibration of the NORM *5651* tube can be checked by changing the CHECK-NORM switch from the NORM position to the CHECK position. If, after the circuit has been standardized by means of the STD-TC switch and the STD ADJ rheostat, the indicator reading of the input signal is the same for the CHECK position as for the NORM position, the indicator is correctly calibrated. A difference in the two readings indicates that the characteristics of at least one of the *5651* tubes have changed and both tubes should be replaced. While it is possible to obtain the same indicator reading when both tubes are in error, this condition is not probable.

A relatively constant input signal for the preceding test is obtained from two thermocouples connected in series opposition, with one couple in close thermal contact with the hot driving motor and the second couple exposed to the colder ambient temperature. This signal is connected to the input of the indicator by putting the INT-TC-EXT switch in the INT position.

Tap points are provided in the potentiometer circuit for checking its accuracy against an external standard cell (1.0190 V points of Fig. 9). These points also provide a means of accurately calibrating the *5651* tubes. However, these checks and calibrations can only be made at temperatures that will not damage the standard cell.

Since the accuracy of standardization depends on the constancy of the resistance of coil E, this coil is made of Evanohm because Evanohm varies less with temperature than manganin over a temperature range of −55 to +55 C.[4] Except for the copper compensating coil, the reference junction coil, and its counterpart D', all other resistors in the potentiometer circuit are of manganin, since the accuracy of measurement depends primarily on the ratios of these resistors remaining constant as the temperature varies rather than on the constancy of their magnitudes.

Performance

Inaccuracies in the indicator readings may be caused by errors in the calibration or temperature compensation of the *5651* tubes and by variations in line voltages. The effect of these errors has been discussed previously. Errors in calibration of the main indicating dial or in the values of the resistances in the potentiometer and associated circuits can be held to less than 0.05 per cent. Adequate electrostatic and magnetic shielding is provided, and normal line transients cause no error in indication. Voltages picked up in the thermocouple leads are attenuated by a factor of 100 at 60 cycles and 700 at 400 cycles.

Performance tests over the entire range of ambient temperatures (−55 to +55 C), line voltage (105 to 125 volts), and line frequency (380 to 420 cycles) show that the instrument

1. Operating as a millivolt indicator (without reference junction compensation) has a resultant error of only ±0.1 per cent.
2. Operating as a temperature indicator (with reference junction compensation and a measuring range of −70 to +60 C) has a resultant error of less than ±0.9 C.

Full-scale balancing time at ambient temperatures from approximately 0 to +55 C is less than 4 seconds. At temperatures below 0 C the balancing time increases as the temperature decreases, but never becomes slower than 10 seconds. The indicator weighs 24 pounds and will withstand the severe shock and vibration tests specified by MIL-E-5272-A.[5]

Conclusions

The air-borne temperature indicator is a rugged, reliable, direct-reading indicator, which, without batteries or standard cells, maintains a low limit of error at all scale readings, for line voltages from 105 to 125 volts (400 cycles) and for all ambient temperatures between −55 and +55 C.

On the Optimum Design of Cathode Followers

L. M. VALLESE
ASSOCIATE MEMBER AIEE

CATHODE followers find wide application in modern electronics because of their simple structure, their fairly distortionless operation, and their low output impedance. Designing for small signal amplification is easy; for large signal amplification a complication is introduced with the requirement that the distortion-free driving range of the control grid be utilized fully. This problem can be solved graphically, but the procedure is cumbersome and of limited application. Its usefulness can be greatly enhanced if it is used merely to check and improve an approximate preliminary design obtained analytically.

For the derivation of such a design the family of plate characteristics of the tube, which is usually a triode, can be represented by means of the bilinear relationship

$$i_b = g_p(e_b + \mu e_{ck} - V_0') \qquad (1)$$

This equation corresponds to a set of straight lines (Fig. 1), having slope g_p and intercept $V_{bk} = -\mu e_{ck} + V_0'$ with the $i_b = 0$ axis; in particular V_0' is the intercept corresponding to $e_{ck} = 0$.

The main purpose of the design consists in determining the values of E_Q, I_Q at the quiescent point so that the grid-to-cathode voltage may be varied between -0.5 V and a value corresponding to a minimum plate current I_{bm}. In addition, the design may be optimized with respect to the power and voltage output, plate dissipation, etc. In the following the cases of a-c and d-c amplifiers will be discussed separately; it will be shown that the design of a-c amplifiers is subject to less restriction than that of d-c amplifiers. The circuit element in the cathode lead of a-c amplifiers can have either a conductive admittance $G_k + j0$ or an inductive admittance $0 - jB_k$, while the corresponding element of d-c amplifiers must have conductive admittance.

A-C Cathode Followers with Conductive Cathode Lead Element

The circuit diagram of a typical a-c cathode follower with conductive cathode lead element is indicated in Fig. 2. The analysis will be limited to the mid-frequency range, disregarding high- and low-frequency effects. For this reason the interelectrode and coupling capacitances will be neglected and the design will be limited to the determination of the quantities G_k, G_L, E_{bb}, E_0, E_s, $(E_{ck})_Q$, E_Q, I_Q. The interpretation of these symbols follows from Figs. 1 and 2; it should be noticed that E_0 and E_s are peak rather than rms values.

The following limitations must be satisfied

$$\left.\begin{aligned} &e_{ck} \le -0.5V \\ &I_{bm} \le i_b \le I_{k\,\max} \\ &E_{bb} \le E_{bb\,\max} \\ &E_Q I_Q \le P_{p\,\max} \end{aligned}\right\} \qquad (2)$$

The last equation applies for zero signal dissipation. Indicating with I_{bM}, the maximum value of the plate current ($I_{bM} \le I_{k\,\max}$) there follows

$$2I_Q = I_{bm} + I_{bM} \qquad (3)$$

$$I_{bM} = g_p(E_Q - E_0 - V_{bk}') \qquad (4)$$

Equation 4 represents a point of the characteristic of i_b versus e_b for $E_{ck} = -0.5$ V and is obtained from equation 1 letting $e_b = E_Q - E_0$ and $V_{bk} = V_{bk}'$. Furthermore

$$I_Q = G_k(E_{bb} - E_Q) = I_{bm} + E_0(G_k + G_L) \qquad (5)$$

From these equations there follows

$$E_Q = V_{bk}' + I_{bm}/g_p + E_0$$

$$E_{bb} = E_Q + I_Q/G_k$$

Finally from the equation $V_{bk} = -\mu e_{ck} + V_0'$ there follows

$$(\mu E_{ck})_Q = V_0' - E_Q + I_Q/g_p$$

The peak input voltage is

$$E_s = E_0 + (E_{ck})_Q - 0.5$$

By elimination of E_Q, I_Q, I_{bm} from equations 3, 4, and 5 one has

$$G_k^2 - \frac{g_p}{2E_0}\left(E_{bb} - 2E_0\left(1 + \frac{G_L}{g_p}\right) - \frac{I_{bM}}{g_p} - V_{bk}'\right)G_k + \frac{g_p}{2}\left(G_L + \frac{I_{bm}}{E_0}\right) = 0$$

which is a relationship among E_{bb}, E_0, G_k, G_L and can be used to determine one

$$G_k=\frac{g_p}{4E_0}\left[E_{bb}-2E_0\left(1+\frac{G_L}{g_p}\right)-\frac{I_{bm}}{g_p}-V_{bk}'\right]\pm \sqrt{\frac{g_p^2}{16E_0^2}\left[E_{bb}-2E_0\left(1+\frac{G_L}{g_p}\right)-\frac{I_{bm}}{g_p}-V_{bk}'\right]^2-\frac{g_p}{2}\left(G_L+\frac{I_{bm}}{E_0}\right)} \qquad (7)$$

or finally

$$E_{bb}=V_{bk}'+I_{bm}\left(\frac{1}{G_k}+\frac{1}{g_p}\right)+2E_0\left(1+\frac{G_L}{2G_k}+\frac{G_L+G_k}{g_p}\right) \qquad (8)$$

Two other important relations are

$$I_{bM}=I_{bm}+2E_0(G_k+G_L)=\frac{2(G_k+G_L)g_pG_k(E_{bb}-V_{bk}')-g_pG_LI_{bm}}{2(g_p+G_k)(G_k+G_L)-g_pG_L} \qquad (9)$$

and

$$P_p=E_QI_Q=\left[E_0\left(1+\frac{2(G_k+G_L)}{g_k}\right)+V_{bk}'+\frac{I_{bm}}{g_p}\right][I_{bm}+E_0(G_k+G_L)]=\left[E_{bb}-\frac{1}{G_k}(I_{bm}+E_0(G_k+G_L)\right][I_{bm}+E_0(G_k+G_L)] \qquad (10)$$

The previous equations will now be applied to a number of practical problems. In particular, numerical design values will be computed for circuits using the *6J5*. From the linearized plate characteristics of this tube (Fig. 3)

$g_p=0.13\times10^{-3}$ mhos, $V_0'=30\ V$, $V_{bk}'=40\ V$
$I_{bm}=0.5\ mA$, $\mu=20$, $I_{k\ \max}=20\ mA$, $E_{bb\ \max}=300\ V$
$P_{p\ \max}=2.5\ w$

DESIGN NO. 1

Given the tube G_k, G_L, E_0, find the minimum necessary value of E_{bb}. Equation 8 is used. That the values of E_{bb}, I_{bm}, and P_p are less than the limit values (equation 2) is checked. Finally $(E_{ck})_Q$ E_{GG}, and E_s are computed.

For example, for a *6J5* tube with $G_k=0.4$ times 10^{-3} mhos, $G_L=10^{-3}$ mhos, $E_0=5\ V$, there follows $E_{bb}=173.5\ V$; in addition, $I_{bM}=14.5\ mA$, $I_Q=7.5\ mA$, $E_Q=155\ V$, $P_p=1.17\ w$, $(E_{ck})_Q=-3.3\ V$, $E_{GG}=151.7\ V$, $E_s=7.7$ V.

DESIGN NO. 2

Given the tube G_k, G_L, find E_{bb} for max E_0 permissible. Since E_0 increases linearly with E_{bb}, it is sufficient to investigate the maximum value of E_0. With respect to the current limitation in equation 2, this is (equation 9)

$$E_0'=\frac{I_{kM}-I_{bm}}{2(G_k+G_L)} \qquad (11)$$

With respect to the power limitation (equation 2), there is from equation 10

$$E_0''=-a+\sqrt{a^2+b} \qquad (12)$$

where

$$a=\frac{[g_p+2(G_k+G_L)]I_{bm}+(G_k+G_L)(g_pV_{bk}'+I_{bm})}{2(G_k+G_L)[g_p+2(G_k+G_L)]}$$

$$b=\frac{g_pP_{pM}-(g_pV_{bk}'+I_{bm})I_{bm}}{(G_k+G_L)[g_p+2(G_k+G_L)]}$$

The lower of the values, equations 11 and 12 is the maximum permissible E_0. Correspondingly, E_{bb} is obtained from equation 8.

For example, for a *6J5* tube with $G_k=0.4$ times 10^{-3} mhos, $G_L=10^{-3}$ mhos, there results $E_0'=7.3\ V$, $E_0''=7.8\ V$.

DESIGN NO. 3

Given the tube G_L, E_0, E_{bb}, find G_k. Equation 7 is used, providing two solutions for G_k. These are checked with respect to the limitations (equation 2). Assuming that both G_k values are permissible, the final choice will be determined on the basis of such considerations as plate power dissipation, peak cathode current, and output admittance.

For example, for a *6J5* tube, given $G_L=10^{-3}$ mhos, $E_0=5\ V$, $E_{bb}=173\ V$, the corresponding values for G_k are as follows

$G_k'=0.4\times10^{-3}$ mhos

$G_k''=0.177\times10^{-3}$ mhos

Both these values are permissible.

DESIGN NO. 4

Given the tube G_L, E_{bb}, find G_k for max E_0. From equation 6, letting $dE_0/dG_k=0$

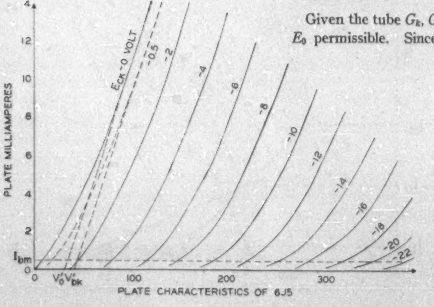

Fig. 3. Plate characteristics of 6J5 tube

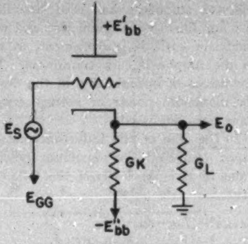

Fig. 5. D-c cathode follower

$$G_k=\frac{g_pI_{bm}}{g_p(E_{bb}-V_{bk}')-I_{bm}}+\sqrt{\frac{g_p^2I_{bm}^2}{(g_p(E_{bb}-V_{bk}')-I_{bm})^2}+\frac{g_p}{2}\left(G_L+\frac{2(g_p+G_L)I_{bm}}{g_p(E_{bb}-V_{bk}')-I_{bm}}\right)}$$

For example, letting $G_L=10^{-3}$ mhos, $E_{bb}=173$ *V*, there results for the *6J5* tube $G_k=2.6$ times 10^{-4} mhos and $E_0=5.09$ *V*.

DESIGN No. 5

Given the tube and E_{bb}, find G_k and G_L for maximum output power $P_L=G_LE_0^2/2$.

This design may be considered of academic interest, since power amplifiers are more efficient with an inductive cathode lead element. However, if the high-frequency response is important, the question of the efficiency might become secondary.

According to equation 6

$$P_L=\frac{G_L}{2}\left[\frac{g_p(E_{bb}-V_{bk}')G_k-(g_p+G_k)I_{bm}}{2G_k(G_k+g_p)+(g_p+2G_k)G_L}\right]^2$$

which is a function of E_{bb}, G_k and G_L. If either G_k or G_L are given, the optimum value of the conductance G_L or G_k is determined respectively with the condition

$$\frac{dP_L}{dG_L}=0 \quad \text{or} \quad \frac{dP_L}{dG_k}=0 \tag{13}$$

If G_k and G_L are both undetermined, the latter two equations must be solved simultaneously. Letting $I_{bm}=0$ to simplify the final expressions, there follows, for G_k given

$$G_{L\ \text{opt}}=2G_k(G_k+g_p)/(2G_k+g_p)$$

and for G_L given

$$G_{k\text{opt}}=\sqrt{g_pG_L/2}$$

Finally, if both G_k and G_L are undetermined, their optimum values are

$$G_k=g_p/\sqrt{2} \qquad G_L=g_p \tag{14}$$

Correspondingly, the peak power output is

$$P_{L\ \text{peak}}=\frac{g_p(E_{bb}-V_{bk}')^2}{16(1+\sqrt{2})^2}$$

It is of interest to point out that the result (equation 14) applies also for grounded cathode amplifiers.

A-C Cathode Followers with Inductive Cathode Lead Element

The circuit diagram of Fig. 4 is now studied; it is assumed that $jB_k=1/j\omega L$ is negligible. The limitations of the design are still expressed by equations 2, where $E_Q=E_{bb}$. The design in the present case is much simplified and reduces to finding I_Q, since E_Q is fixed. The design equations are

$$I_Q=I_{bm}+G_LE_0$$

$$I_{bM}=g_p(E_{bb}-V_{bk}'-E_0)=2I_Q-I_{bm}$$

$$\mu(E_{ck})_Q=(V_0'-E_{bb}+I_Q/g_p)$$

$$E_s=E_0+(E_{ck})_Q-0.5$$

Eliminating I_Q between the first and the second equation results in

$$g_p(E_{bb}-V_{bk}')-I_{bm}=E_0(2G_L+g_p) \tag{15}$$

From this equation, if E_{bb} and G_L are given

$$E_0=\frac{g_p(E_{bb}-V_{bk}')-I_{bm}}{2G_L+g_p} \tag{16}$$

and if E_{bb} and E_0 are given

$$G_L=\frac{g_p(E_{bb}-V_{bk}'-E_0)-I_{bm}}{2E_0}$$

The maximum possible value of E_0 for given E_{bb} occurs when $G_L=0$ and is

$$E_{0\ \max}=E_{bb}-V_{bk}'-I_{bm}/g_p$$

On the other hand, when $G_L\neq0$, the maximum possible value of E_0 is

$$E_{0\ \max}=(I_{kM}-I_{bm})/2G_L$$

according to equations 15 and 16.

As an example, given a *6J5* tube with $E_{bb}=200$ *V*, $G_L=10^{-3}$ mhos, there follows $E_0=9.6$ *V*, $I_Q=10.1$ *mA*, $(E_{ck})_Q=-9.7$ *V*. The maximum possible value of E_0 for the given value of G_L is 9.75 *V*; the maximum possible value of E_0 for $G_L=0$ is 156 *V*.

An interesting problem is the determination of the optimum value of G_L for maximum power output.

$$P_L=G_LE_0^2/2=G_L(g_p(E_{bb}-V_{bk}')-I_{bm})^2/2(2G_L+g_p)^2$$

and letting $dP_L/dG_L=0$, there follows $2G_L=g_p$, which is the same result that applies for grounded cathode amplifiers. Correspondingly, the maximum power output is

$$P_{L\ \text{peak}}=\frac{g_p(E_{bb}-V_{bk}')^2}{16}$$

D-C Cathode Followers

A typical circuit for the d-c cathode follower is indicated in Fig. 5. For generality it has been assumed that $E_{bb}'\neq E_{bb}''$.

One of the conditions of the design is that the cathode be at ground potential. Correspondingly

$$E_Q=E_{bb}' \qquad I_Q=G_kE_{bb}'' \tag{17}$$

By application of Thévenin's theorem the circuit of Fig. 5 can be modified into that of Fig. 6(A), with

$$G'=G_k+G_L \qquad E'=G_kE_{bb}''/(G_k+G_L)$$

The latter circuit is equivalent to that of Fig. 6(B) which is similar to the circuit of an a-c cathode follower with zero load admittance G_L.

The limit conditions of operation are

$$E_{ck}\leq-0.5\ V$$

$$I_Q=G_kE_{bb}''\leq(I_{kM}+I_{bm})/2 \tag{18}$$

$$P_p=E_{bb}'I_Q\leq P_{p\ \max} \tag{19}$$

The design equations are

$$E_{bb}'=E_0+V_{bk}'+I_{bM}/g_p$$

$$=V_{bk}'+E_0(1+2(G_k+G_L)/g_p) \tag{20}$$

$$I_Q=[I_{bm}+g_p(E_{bb}'-V_{bk}'-E_0)]/2 \tag{21}$$

$$=I_{bm}+E_0(G_k+G_L) \tag{22}$$

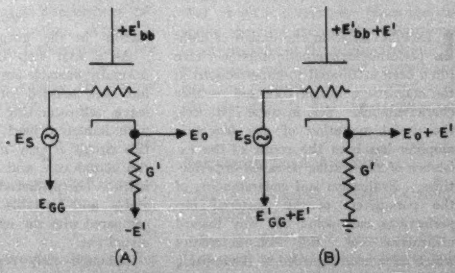

Fig. 6. D-c cathode follower

$$\mu(E_{ck})_Q = V_0' - E_{bb}' + I_Q/g_p \qquad (23)$$

$$E_s = E_0 + (E_{ck})_Q - 0.5 \qquad (24)$$

In general E_0 and G_L are prescribed, and the purpose of the design consists in choosing tube and evaluating E_{bb}', E_{bb}'', and G_k.

The choice of the tube is determined by the maximum voltage output E_0 that it can deliver in accordance with the limitations (equations 18 and 19). The upper limit of E_0 is obtained letting G_k approach zero. Combining equations 18 and 22

$$E_{0\,\max}' = (I_{kM} - I_{bm})/2G_L \qquad (25)$$

On the other hand, combining equations 19, 20, and 22, there results

$$[E_0(1+2(G_k+G_L)/g_p) + V_{bk}'](E_0(G_k+G_L) + I_{bm}) \le P_{pM}$$

wherefrom there follows

$$E_{0\max}'' = \frac{-g_p V_{bk}'}{2(g_p+2G_L)} + \sqrt{\frac{g_p P_{p\max}}{G_L(g_p+2G_L)} + \left(\frac{g_p V_{bk}'}{2(g_p+2G_L)}\right)^2} \qquad (26)$$

The lower of the values equations 25 and 26 should be larger than the required E_0.

After the tube has been selected, E_{bb}' is evaluated. The upper limit of E_{bb}' again is determined in accordance with the limitations (equations 18 and 19). Combining equations 18 and 21

$$E_{bb}' \le E_0 + V_{bk}' + (I_{kM} - I_{bm})/g_p \qquad (27)$$

On the other hand, combining equations 19 and 21, there results

$$E_{bb}' \le \frac{1}{2}\left(V_{bk}' + E_0 - \frac{2I_{bm}}{g_p}\right) + \sqrt{\frac{1}{4}\left(V_{bk}' + E_0 - \frac{2I_{bm}}{g_p}\right)^2 + \frac{2P_{pM}}{g_p}} \qquad (28)$$

In general, the value of E_{bb}' is chosen in dependence of the available power supply, so that the limitations (equations 27 and 28) are satisfied.

After the value of E_{bb}' has been determined, equations 21 and 22 provide respectively I_Q and G_k. Finally, the value of E_{bb}'' is obtained from equation 17, and the values of $(E_{ck})_Q$ and E_s are computed from equation 23 and 24 respectively.

For example, consider the design of a d-c cathode follower with $E_0 = 8$ V, $G_L = 10^{-3}$ mhos. For the tube *6J5* equations 25 and 26 provide respectively

$$E_{0\max}' = 9.75 \text{ V}$$

$$E_{0\max}'' = 11.2 \text{ V}$$

Therefore the *6J5* tube is suited for the present design. According to equations 27 and 28, the upper limit of E_{bb}' is the lower of the following values: $E_{bb}' \le 196$ V, $E_{bb}' \le 214$ V.

Letting $E_{bb}' = 180$ V, equation 21 provides $I_Q = 9$ mA, and equation 22 gives $G_k = 0.06$ times 10^{-3} mhos. Finally $E_{bb}'' = 150$ V and $(E_{ck})_Q = -4$ V, and $E_s = 11.5$ V.

Summary

An analytical procedure to obtain a preliminary design of large signal cathode follower amplifiers has been described. A-c amplifiers with conductive and with inductive cathode lead element, as well as d-c amplifiers, are considered. The conditions of optimization of the design for maximum power or voltage output have been discussed.

In the case of the inductance-capacitance amplifier the maximum possible value of E_0 is the lower of the following ones

$$E_{0\max}' = (I_{kM} - I_{bm})/2G_L$$

$$E_{0\max}'' = (P_{p\max} - E_{bb}I_{bm})/G_L E_{bb}$$

In the case of the d-c amplifier the design for max P_L gives

$$G_k \cong 0,\ G_L = G_k + g_p/2$$

$$P_{L\max} = g_p(E_{bb}' - V_{bk}')^2/_{16}$$

Inductive Load Instability in Magnetic Amplifiers

H. I. LEON
NONMEMBER AIEE

ALLEN B. ROSENSTIEN
ASSOCIATE MEMBER AIEE

LIMITATIONS in the design of high-performance magnetic amplifiers have often been attributed to imperfections in the magnetic amplifier core and rectifier characteristics. Yet, in some instances, the useful operation of the magnetic amplifer has been the result of the existence of these same so-called imperfections. Evaluation and understanding of the parameters of the material imperfections can point the way toward utilization of the characteristics which have been regarded as the limiting factors in the amplifier performance.

As a first step in this direction, a normally unstable amplifier configuration has been selected for analysis, the full-wave, self-saturating magnetic amplifier with inductive load. The behavior of this circuit is very much dependent on the actual core and rectifier characteristics. The predicted boundary between stable and unstable operation will be compared with the experimentally determined one.

Although early reports on magnetic amplifiers have noted instabilities in circuits with ostensibly less than 100-percent feedback, it is only recently that articles have begun to appear which describe the mechanism of these instabilities. The effects of core material on stability has been investigated.[1] Instability caused by inductive loads has been mentioned in several articles[2-6] and has been avoided in one of several ways. The inductive load is tuned to resonance to present a capacitive reactance; a rectifier or rectifier bridge is added to the load

circuit; the amplifier circuit is changed to a more stable configuration; or the control circuit constraint is made very high or inductive loads are avoided altogether.

The purpose of this paper is to examine the mechanism of the inductive instability to predict the unstable domain and to seek more efficient stability methods. To develop the practical magnetic amplifier circuit analysis, it has been expedient to analyze first the completely idealized amplifier utilizing "perfect" rectifiers and magnetic cores. Then one idealized circuit element or material characteristic at a time has been changed to a more realistic one and the system reanalyzed. This procedure has been continued until practically all of the nonlinearities of the amplifier elements have been considered and the performance predicted from the mathematical model of the system offered a reasonable representation of the actual system performance.

Nomenclature

C = capacitance
E = direct voltage, peak alternating voltage
H = magnetizing force
I = direct current
L = inductance
N = number of turns
R = resistance from gate side
R_b = loop back resistance
R_e = reflected control circuit resistance
R_f = loop forward resistance
T = time constant
$Q = L/R$
Z = impedance
a = turns ratio
e = voltage
i = current
i_L = load current
n = integer
r = resistance
t = time
x = angle
α = ratio
β = feedback ratio
γ = ratio
ϕ = flux
θ = angle
ω = angular frequency
τ = time constant
$\Delta(\ )$ = change in $(\ )$

Subscripts

ac = alternating current
c = control, coercive
g = gate
s = saturation
1 = loop 1
2 = loop 2

Idealized Circuit Analyses

Consider the operation of the idealized full-wave, self-saturating magnetic amplifier, as shown in Fig. 1. The rectifiers have zero forward resistance, infinite back resistance, and no capacitance. The magnetic cores have either the single-valued characteristic, shown in Fig. 2(A), or the double-valued characteristic, shown in Fig. 2(B). The slopes of these characteristics are either zero or slightly positive in the saturated zones, and large (but finite) in the unsaturated zones. Loop resistances R_1 and R_2 are negligible.

The core winding in the load circuit is called the gate winding, the other winding is called the control winding. The term gate may refer to either the core or the winding. Whenever a voltage appears across the gate winding, the core flux must change in accordance with

$$e_g = N_g \frac{d\phi}{dt} \tag{1}$$

The change in flux is

$$\Delta\phi = \phi(t_2) - \phi(t_1) = \frac{1}{N}\int_{t_1}^{t_2} e\,dt \tag{2}$$

A change of flux may be referred to as a $\Delta\phi$ or its equivalent volt-seconds as calculated from this equation. A core is said to absorb voltage whenever the core flux is changing.

For a sinusoidal voltage, the change in flux for a half-cycle is

$$\Delta\phi = \int_0^{\pi/\omega} E \sin \omega t\,dt = \frac{2E}{N\omega} \tag{3}$$

If the change in flux is from full negative to full positive saturation, then

$$E = N\omega\phi_s \tag{4}$$

where ϕ_s is the saturation flux. In this analysis, the supply voltage will be adjusted to this value.

Whenever a gate saturates, it will be considered as a short circuit across any of its windings. Whenever a gate is not saturated, it will be considered as a perfect transformer. When a core is changing flux in the negative direction, i.e., so that negative loop current will attempt to flow if the core reaches negative saturation, it will be called the reset interval for that core. When a core is changing flux in the positive direction, it will be called the set interval for that core. A core is completely reset when the flux has reached the bias value, i.e., the value of flux corresponding to the d-c ampere-turns in the control winding on the descending branch of the hysteresis loop. A completely reset core will have zero current in its gate winding. A gate voltage that tends to reset the core further will cause a current flow in the reverse rectifier direction.

The criterion for stability to be used is that the steady-state load current shall change incrementally for an incremental change in load current. Six magnetic amplifier circuits having progressively fewer ideal elements or characteristics will be analyzed to determine the factors which influence inductive load instability. In the description of the last circuit, case VI, a practical magnetic amplifier circuit having a reactive load and finite control-circuit resistance is discussed qualitatively. Then a quantitative analysis of that circuit is presented. Since the unstable region of operation usually occurs experimentally at the minimum load current point, only small load currents and low firing angles will be considered in all cases in order to find the boundary of stability.

Resistance Load Analyses

Case I. Nonzero Control-Circuit Resistance

For the bias point, shown in Fig. 2 (not quite to $-\phi_s$), wave forms of gate

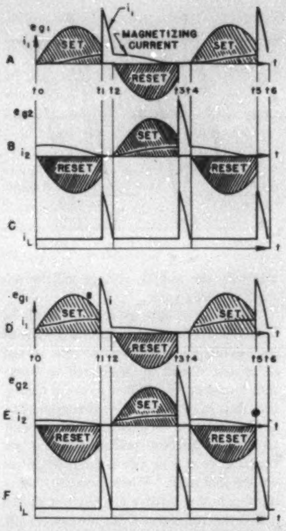

Fig. 3. Wave forms for cases I and II, a resistance load and nonzero control-circuit resistance with (D, E, F) and without (A, B, C) magnetic hysteresis

voltage and load current are shown in Fig. 3. Curves *A*, *B*, and *C* are for the single-valued characteristic of Fig. 2(A) and curves *D*, *E*, and *F* are for the double-valued characteristic of Fig. 2(B). The initial conditions have gate 1 starting at the bias flux and gate 2 at positive saturation.

From t_0 to t_1, gate 1 sets and gate 2 resets. Magnetizing currents flow in both gate windings. At t_1, gate 1 saturates and $i_1=e_1/R_L$. Double reset voltage is now impressed on loop 2 as saturated gate 1 is considered a short circuit. However, gate 2 has reset completely at t_1 and the rectifier blocks any negative current preventing any further change in flux.

At t_2, the current i_1 decreases to the value at which gate 1 emerges from the saturated zone. Gate 1 now is subjected to reset volt-seconds and gate 2 to set volt-seconds. No control-circuit current is induced because the voltages across both gates are always equal and opposite.

The set volt-seconds are equal to the area under the e_{g1} curve from t_0 to t_1. The reset volt-seconds are equal to the area under the e_{g2} curve in the same interval. If, for some reason, reset was inhibited so that gate 2 did not attain the bias flux at t_1, then double reset voltage is available in the interval t_1 to t_2. This excess of reset volt-seconds insures complete reset before the end of the half-cycle. This circuit is inherently stable.

CASE II. ZERO CONTROL-CIRCUIT RESISTANCE

The zero value of control-circuit resistance may be obtained without disturbing the value of i_c by an additional, short-circuited control winding. Wave forms for this case are identical with those for case I. Operation differs in only one respect: during the interval t_1 to t_2, gate 1 is saturated and short-circuits gate 2 from the control side. At t_2, however, gate 2 is completely reset, and the rectifier blocks any reverse current. There is consequently no change in steady-state circuit operation from case I.

Inductive Load Analyses

Cases I and II have shown that, with resistive loading, the set and reset volt-seconds are always equal and the amplifier is inherently stable. The essential elements of the inductive load instability can be easily visualized from Fig. 2. Consider the commutation time interval when the load current is transferring from loop 1 to loop 2. If the load is inductive, a voltage is induced in the inductance that attempts to maintain the current flow at previous magnitudes. If the polarities of the voltages are noted around both loop 1 and loop 2, it can be seen that the voltage across the inductance adds additional set volt-seconds to gate 2 and subtracts from the reset volt-seconds available to gate 1. In contrast, the polarity across a capacitive load at commutation is exactly opposite from that of the inductive load with the result that set volt-seconds are reduced and reset volt-seconds increased. Capacitive loading is, therefore, inherently quite stable.

CASE III. PURE INDUCTANCE LOAD AND ZERO CONTROL-CIRCUIT RESISTANCE

The case of pure inductance load and zero control-circuit resistance cannot be constructed with practical materials. The theoretical wave forms are given in Fig. 4 for completeness. At t_0, gate 1 is started at the bias point and gate 2 at positive saturation. From t_0 to t_1, gate 1 sets and gate 2 resets. Wave forms for negligible magnetizing currents are shown in Fig. 4(A), (B), and (C). At t_1, gate 1 saturates and gate 2 is completely reset. During the interval t_1 to t_2, the rectifier prevents any change in loop 2. Load current flows in loop 1 as

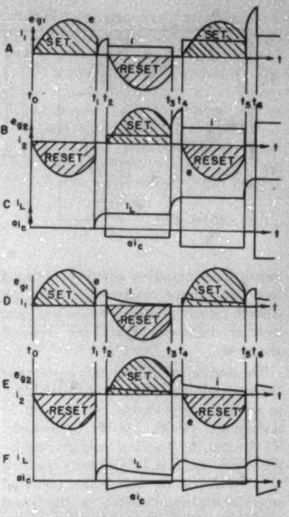

Fig. 4. Wave forms for cases III and IV (A, B, C), inductance load and zero control-circuit resistance, and for case IV (D, E, F), inductance-resistance load and zero control circuit resistance

$$i_L(t)=i_1(t_1)+\frac{E}{\omega L}(\cos\omega t_1-\cos\omega t);\quad t_1<t<t_2 \tag{5}$$

At t_2, the supply voltage changes sign and set voltage is applied to loop 2. At this instant, load current is quite large, in fact at its maximum value, and gate 1 remains saturated. The control winding of gate 2 is short-circuited by the control winding on gate 1. Load current immediately divides between loops 1 and 2; see Appendix III. Control-circuit current flows, equal and opposite to the loop current, so that the net ampere-turns on each gate are zero (except for magnetizing current).

Gate 1 resets and gate 2 sets at normal voltage starting from t_2 independently of the load current which is maintained constant from t_2 to t_3 by the dissipationless, inductive circuit; see Appendix III. At t_3, gate 2 saturates and gate 1 flux has attained the bias value. However, the rectifier in loop 1 cannot block because the rectifier carries a large positive current. The voltage in loop 1 is negative and has double amplitude because gate 2 is a short circuit. Hence, the current in the outside impedanceless loop, i.e., through both gates and power supplies, immediately jumps to the value of the loop current, reducing the current in loop 1 to zero and transferring the total load current to loop 2. The rectifier in loop 1 prevents any further change in loop 1 and gate 1 is clamped at the bias-flux point. Load current from loop 2 now increases as

$$i_L(t)=i_2(t_3)+\frac{E}{\omega L}(\cos\omega t_3-\cos\omega t);\ t_3<t<t_4 \tag{6}$$

At t_4, the supply voltage again changes sign and loop 1 becomes conducting. However, the control side of gate 1 is still short-circuited and, as before, the load current divides equally between loops 1 and 2 and remains constant from t_4 to t_5. Current equal and opposite to the loop currents flows in the control circuit. Since the load current increases stepwise each half-cycle without bound, this circuit is unstable.

Case IV. Inductance and Resistance Load, Zero Control-Circuit Resistance

The zero control-circuit resistance may be realized, as discussed in case II. In this case, as shown in curves *D*, *E*, and *F* of Fig. 4, the current build-up in the interval t_1 to t_2 is of the form

$$i_L(t)=i_1(t_1)\epsilon^{-\frac{\omega}{Q}(t-t_1)}+\frac{E}{Z}\Big[\sin(\omega t-\tan^{-1}Q)$$
$$-\epsilon^{-\frac{\omega}{Q}(t-t_1)}\sin(\omega t_1-\tan^{-1}Q)\Big] \tag{7}$$

where $Q=\omega L/R$ and $Z^2=\omega^2L^2+R^2$. At t_2, the load current divides equally between the two loops but does not remain constant as in case III. Rather, it decays with a time constant $T=L/R=Q/\omega$ from t_2 to t_3 while the gates set and reset at normal voltage. At t_3, $i(t_3)=i(t_2)\epsilon^{-\frac{\omega}{Q}(t_3-t_2)}$ and the current buildup is again given by equation 7.

For $Q>0$, the load current at the voltage reversal point continues to increase each half-cycle until the transient increase during the conducting period is equal to the current decay during the previous half-cycle, that is

$$i_L[\omega t=(n+1)\pi]=i_L[\omega t=n\pi] \tag{8}$$

Let θ be the firing angle ($\theta/\omega=t_2-t_1$). Then the steady-state value of current at the voltage reversal point, obtained by combining equation 7 with conditions of equation 8, is

$$i_0=\frac{E}{Z(1-\epsilon^{-\pi/Q})}[\sin(\tan^{-1}Q)-\epsilon^{-\theta/Q}\sin$$
$$(\theta+\tan^{-1}Q)] \tag{9}$$

Since there is a definite value of output current and firing angle for each value of bias the circuit is stable.

Case V. Resistance and Inductance Load and Nonzero Control-Circuit Resistance

This case resembles the last two cases for the time interval t_0 to t_2; see Fig. 5. Gate 1 saturates at t_1 as gate 2 attains the bias-flux level. Loop 1 conducts and the load current is the same as in case IV. Loop 2 is blocked from further change by rectifier action. At t_2, the supply voltage reverses in sign and loop 2 has double set voltage. Now, however, the equivalent circuit is as illustrated in Fig. 6(A).

Gate 2 is assumed to be a perfect transformer and is replaced by the equivalent resistance $R_c=r_c/a^2$. The transformed set voltage of gate 2 causes a current i_2/a to flow in the control winding which, in turn, allows a current i_2 to flow in the gate 2 power winding. Then, for $i_2\leq i_1$

$$e=e_L=(i_1+i_2)R+L\frac{d}{dt}(i_1+i_2)\text{ and}$$
$$-e=i_2R_c+e_L \tag{10}$$

Hence

$$-2e=i_2R_c\text{ and }e=L\frac{di_L}{dt}+Ri_L \tag{11}$$

where $i_L=i_1+i_2$. For the condition $i_1=i_2$

$$i_L=2i_1=-4e/R_c \tag{12}$$

In the interval t_2 to t_3, gate 1 is still saturated and is considered a short circuit with the result that the load is still connected directly to the voltage supply, and load current continues to be expressed by equation 7. Loop 2 current increases as $i_2=2e/R_c$ to the point t_3, as shown in Figs. 5 and 6(B) ($i_1=i_2=1/2\ i_L$), when core 1 leaves the region of saturation. Beyond t_3, the load current remains evenly divided between the two loops because of the control-circuit coupling (see Appendix III) and decays as

$$i_L(t)=i_L(t_3)\epsilon^{-(t-t_3)/T};\ t_3<t<t_4 \tag{13}$$

where

$$T=\frac{L}{R+R_c/4}=\frac{L}{R+r_c/4a^2} \tag{14}$$

During the interval t_3 to t_4, gate 1 remains saturated. Gate 2 sets at a voltage, i.e., double voltage. At t_4, gate 1 leaves the saturated state and resets at normal voltage while gate 2 sets at normal voltage. At t_4, gate 2 saturates earlier in this half-cycle than did gate 1 during the preceding half-cycle because the interval of double set voltage from t_2 to t_3 has caused gate 2 to absorb the necessary amount of volt-seconds in a shorter interval. This change in the set interval caused by the double set voltage experienced during current commutation is a fundamental factor in producing instability. It should be noted that the double set voltage is caused by the load voltage adding set volt-seconds to the unsaturated core when the supply voltage reverses polarity and the load current starts to decline.

Gate 1 now acts as a perfect transformer and is replaced by the reflected control-circuit resistance R_c. Just before gate 2 saturates, the current in loop 1 is

$$i_1(t_4)=\frac{2e(t_3)}{R_c}\epsilon^{-(t_4-t_3)/T};\ T=\frac{L}{R+R_c/4} \tag{15}$$

At t_4, double voltage is impressed across R_c and a current $i=2e(t_4)/R_c$ is possible in the outer loop, provided the rectifiers

Fig. 5 (below). Wave forms for case V, an inductance-resistance load and nonzero control-circuit resistance

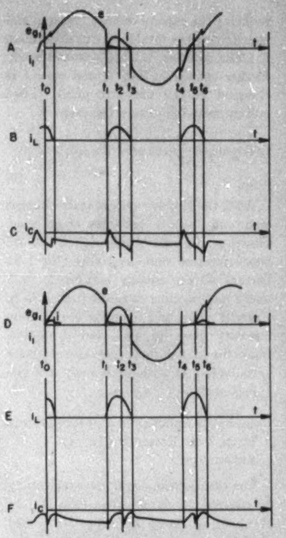

Fig. 8 (right). Wave forms from the experimental amplifier having inductive loading, finite control-circuit resistance, and either selenium (A, B, C) or germanium (D, E, F) rectifiers

do not block. To determine what loop 1 current does, consider the ratio

$$\frac{i}{i_1}(t_4^-)=\frac{e(t_4)}{e(t_3)\exp[-(t_4-t_3)/T]} \tag{16}$$

But $e(t_4)>e(t_3)$ from elementary consideration of the bias flux and gate voltage relations. Hence, $i>i_1$, and loop 1 current tends to become negative. Whatever load current remains at t_4 switches to loop 2 and continues to decay with a new time constant $T=L/R$, and a new transient load current, given by equation 7, starts. In the practical circuit, T is large enough so that the current quickly decays practically to zero for small firing angles. The previous control-circuit current $1/2\ i_L$ is immediately extinguished.

Meanwhile, double voltage becomes available to reset gate 1. The induced voltage in the control winding of gate 1 creates a circulating current i_c such that the reflected voltage drop $i_c r_c$ is equal to $2e$. The corresponding current ai_c subtracts from the magnetizing current of (the not quite reset) core 1. The rectifier in loop 1 will block when ai_c exceeds i_{mag}, in which case i_{mag} will switch to the control circuit and decay exponentially until it equals the (decreasing) value $2e/R_c$. At this point, the rectifier starts to conduct positive current and gate 1 resets at double voltage until the voltage reverses sign. If r_c is sufficiently large, the ai_c may not exceed i_{mag} and gate 1 resets at double voltage for the complete interval t_3 to t_4. Although effects caused by magnetizing currents may be discussed, they will be neglected in the analysis.

At t_5, the supply voltage changes sign again and loop 1 becomes conductive. The load current continues smoothly as before up to t_6 when the gate currents in the outside loop, increasing sinusoidally in the interval t_5 to t_6, become equal to $i_L/2$. During the interval t_5 to t_6, gate 1 sets at double voltage and gate 2 does not reset at all. The cycle continues as in the previous half-cycle, and the output current would eventually assume a constant value similar to case IV if the firing angle did not change. However, the reset volt-seconds are less than the set volt-seconds in the following cycle and the firing angle does change. Consequently, the load current increases each half-cycle causing circuit instability for any $Q>0$. It should be emphasized that ideal rectifiers are necessary for this circuit to be unstable with all degrees of inductive loading.

The restriction of the double reset volt-seconds, stated in the foregoing, is important for it emphasizes the role of the control-circuit impedance when the core magnetizing current is considered in a practical case. If, for example, R_c were very large, the discharge of the magnetizing current of gate 1 through R_c would cause a large transient voltage to appear across gate 1 with the result that the gate would continue to reset; the additional reset volt-seconds are a stabilizing influence. In the limit, if $R_c=\infty$, the circuit will be stable for any Q.

CASE VI. PRACTICAL CIRCUIT HAVING A RESISTIVE AND INDUCTIVE LOAD AND NONZERO CONTROL-CIRCUIT RESISTANCE

In any practical circuit, there are several complicating influences. Loop resistance decreases the voltage across the gate by its IR drop, and rectifier leakage allows some additional reset beyond the bias point. The actual magnetic and rectifier characteristics are much more complicated than the postulated ones. Rectifier capacitance has an appreciable effect.

Experimentally, the salf-saturating, full-wave magnetic amplifier with an RL load is stable in the region of low Q loads and high control-circuit resistance. It is interesting to note that, for most of the ideal cases previously discussed, instability results for any value of Q. It is the factors that are neglected in the idealized system that provide some degree of stability. These are the actual rectifier and core characteristics.

In the practical circuit, the magnetic characteristics consist of a continuous family of minor asymmetrical hysteresis loops, as indicated in Fig. 2(C). Rectifiers have resistance characteristics, as shown in Fig. 7. The operation of a circuit, considering some of these actual characteristics, is shown in Fig. 8. The voltage across gate 2 is no longer a sine wave when the rectifier characteristic is in a region of high resistance. This region occurs for currents less than a small, positive value; see Fig. 7. The rectifier current actually reverses during the last half of the reset interval t_0 to t_2. The rectifier resistance becomes large during this interval, and some of the reset voltage is consumed in rectifier voltage drop. The locus of ϕ versus 1 for gate 2 is one that cuts across the family of minor loops as the rectifier consumes its share of the voltage.

From t_1 to t_3, load current flows from loop 1. The forward rectifier resistance is added to the load resistance. At t_1, gate 1 conducts, causing double reset voltage to appear in loop 2. This double reset voltage divides between the back rectifier impedance and the reflected control-circuit resistance. The selenium rectifiers have appreciable capacitance so that, initially, the full double voltage appears across R_c, see t_1 in Fig. 8, curve *A*. This double voltage decreases rapidly as the rectifier capacitance quickly charges. At t_2, the supply voltage reverses sign and double set voltage is applied to loop 2. The rectifier resistance of loop 2 does not decrease immediately to a low value not only because of the slight positive current required to move the operating point on the rectifier characteristic to a region of low resistance, but also because the rectifier capacitance, effectively in parallel with the rectifier resistance, perpetuates the actual rectifier current in the negative direction beyond the voltage reversal point; see Appendix IV. When the rectifier current is sufficiently positive, the rectifier resistance decreases to its small forward value. Load current switching from loop 1 adds positive current to loop 2 and causes the rectifier resistance to decrease to a low value only slightly beyond the voltage reversal point. From t_2 to t_3, load current continues to flow in loop 1. At t_3, some load current switches to loop 2 (see case V) but the time constants with the selenium cells are so small that the oscillogram response is not discernible.

Germanium rectifiers have negligible capacitance, and the double loop voltage divides between the back rectifier resistance and the reflected control-circuit resistance. A galvanometer with a high-frequency response was used to record gate current of the amplifier employing germanium rectifiers. The load current that switched from one loop to the other is discernible in Fig. 8, curve *D*.

At t_3, the load current has decreased to zero, neglecting magnetizing current. Gate 1 leaves the saturated zone beyond t_3, and both gates absorb voltage at a normal rate. Magnetizing currents alone flow in both loops in the interval t_3 to t_4.

At t_4, gate 2 saturates at a different time in the half-cycle than the corresponding saturation time for gate 1 during the preceding half-cycle because of the intervals of modified set and reset voltages. During the interval t_4 to t_5, loop 1 has double reset voltage but the magnetizing current is in the region of high rectifier resistance, and voltage division occurs again. The circuit operation proceeds in this manner.

It is seen that, for other than perfect rectifiers, there are several opposing effects present. There is the interval of inhibited double set voltage during the commutation period caused by the set voltage division between forward rectifier resistance and reflected control-circuit resistance, and the interval of inhibited reset caused by the reset voltage division between the reflected control-circuit resistance and either back resistance of the germanium rectifier or back impedance of the selenium rectifier. In addition, there is the series *IR* drop which removes more set voltage than reset voltage because of the larger magnetizing currents during set: rectifier leakage, which does allow some reset beyond the bias point for sufficiently large reflected control resistance; and selenium rectifier capacitance which creates a lag in the application of double set voltage by holding the rectifier in a region of high resistance beyond the point of voltage reversal.

Analytical Determination of Stability Boundary

To analyze the practical circuit of case VI, it will be necessary to determine experimentally the initial conditions of operation and to show the exact basis of analysis. The particular full-wave, self-saturating magnetic amplifier used is described in Appendix I.

When the control-circuit resistance is adjusted to the critical value and the control current is slowly reduced, tiny load current pulses appear before the amplifier triggers; see Fig. 9. The firing angle for these pulses is about 20 degrees. In the analysis for the boundary of stability, the firing angle appears in the equations, and this value of 20 degrees is used in the calculations.

At the minimum output conditions, the gate voltage differs from the supply voltage. There is loss of reset volt-seconds caused by the *IR* drop in the forward loop resistance and the voltage wave forms are modified somewhat by the nonsinusoidal magnetizing currents. Whatever the exact situation may be, there does exist a balance between set and reset volt-seconds at the initial stable value of load current. The analysis will proceed from this point. The voltage wave forms will be restored to sinusoidal shapes to simplify the computations.

For small values of θ/Q, where θ is the firing angle, it is possible to estimate the commutation angle y; see Appendix II. This angle, which is the angle beyond the supply voltage reversal point for which load current persists, is given by

$$y=\theta\left(1-\frac{2\theta}{3Q}-\frac{4QR}{\theta R_c}\right) \qquad (17)$$

This equation is correct within 2 per cent for $\theta/Q<0.2$, and $R_c>500\ R$. For example, to ensure this accuracy for $\theta=20$ degrees, Q must be greater than 0.5.

With the circuit of case VI, shown in Fig. 10, the following are postulated: a constant forward rectifier resistance R_f, a constant back rectifier resistance R_b, and no rectifier capacitance. Let the first half-cycle be stable, so that

$$\theta_2^2=\theta_1^2\left(1-\frac{2\theta_1}{3Q}-\frac{4QR_1}{\theta_1 R_c}\right)^2$$
$$\cong\theta_1^2\left(1-\frac{4\theta_1}{3Q}-\frac{8QR_1}{\theta_1 R_c}\right) \qquad (18)$$

within the accuracy of the approximation, and $\theta_2=\theta_0$; see Fig. 11. R_1 is the total forward resistance of loop 1.

For the duration of θ_2, gate 1 sets at a voltage

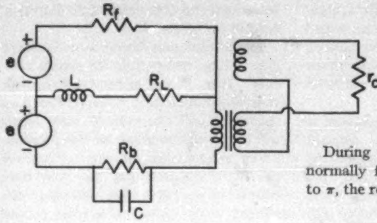

Fig. 10. Equivalent circuit for one phase of operation in case VI

$$e_1=(2e-i_2R_f)\frac{R_c}{R_c+R_f}\backsimeq 2e\frac{R_c}{R_c+R_f} \qquad (19)$$

The current i_2 decreases during the commutation period because some current switches to loop 1, and the load current decays. Consequently, i_2R_f remains small throughout the interval and it will be neglected in the analysis.

Gate 2 does not reset at all during this interval. The change of flux in the gate for an applied voltage of $e=E\sin\omega t$ is

$$\Delta\phi=\frac{1}{N}\int_{t_1}^{t_2}E\sin\omega t\,dt=\frac{1}{\omega N}\int_{x_1}^{x_2}E\sin dx \qquad (20)$$

$$=\frac{E}{\omega N}(\cos x_1-\cos x_2) \qquad (21)$$

Let $E=N\omega\phi_s$, the usual operating condition. Then

$$\Delta\phi=\phi_s(\cos x_1-\cos x_2) \qquad (22)$$

For $x_1=\theta_2$, then $x_2=\pi-\theta_3$. When θ_2 and θ_3 are small, the change in flux from θ_2 to $\pi-\theta_3$ is

$$\Delta\phi=2\phi_s\left(1-\frac{\theta_2^2}{4}-\frac{\theta_3^2}{4}\right) \qquad (23)$$

The complete change of flux in gate 1 during the interval 0 to π is

$$\Delta\phi_1=2\phi_s\left(1-\frac{\theta_2^2}{4}-\frac{\theta_3^2}{4}\right)+$$
$$2\phi_s\frac{R_c}{R_c+R_f}(\cos\theta-\cos\theta_2) \qquad (24)$$
$$=2\phi_s\left(1-\frac{\theta_2^2}{4}-\frac{\theta_3^2}{4}\right)+2\phi_s\frac{R_c}{R_c+R_f}\frac{\theta_2^2}{2}$$

During this half-cycle, gate 2 resets normally from θ_2 to $\pi-\theta_3$. From $\pi-\theta_3$ to π, the reset voltage is

$$-e_2=(2e-i_1R_f)\frac{R_c}{R_c+R_b}\backsimeq 2e\frac{R_c}{R_c+R_b} \qquad (25)$$

The change in flux of gate 2 is

$$-\Delta\phi_2=\phi_s[\cos\theta_2-\cos(\pi-\theta_3)]+2\phi_s[\cos(\pi-\theta_3)-\cos\pi]\frac{R_c}{R_c+R_b}$$
$$=2\phi_s\left(1-\frac{\theta_2^2}{4}-\frac{\theta_3^2}{4}\right)+2\phi_s\frac{R_c}{R_c+R_b}\frac{\theta_3^2}{2} \qquad (26)$$

The boundaries of stability are determined by

$$\Delta\phi_1=-\Delta\phi_2 \text{ and } \theta_1=\theta_3 \qquad (27)$$

Substituting equations 18, 24, and 26 into the conditions of equation 27, the following conditional equation for stability is obtained

$$2\phi_s\left(1-\frac{\theta_2^2}{4}-\frac{\theta_3^2}{4}\right)+2\phi_s\frac{R_c}{R_c+R_f}\frac{\theta_1^2}{2}\times$$
$$\left(1-\frac{4\theta_1}{3Q}-\frac{8QR_1}{\theta_1R_c}\right)=2\phi_s\left(1-\frac{\theta_2^2}{4}-\frac{\theta_3^2}{4}\right)+$$
$$2\phi_s\frac{R_c}{R_c+R_b}\frac{\theta_3^2}{2} \qquad (28)$$

The terms involving the interval of normal set and reset, θ_2 to $\pi-\theta_3$, cancel and the flux balance reduces to that of equating set volt-seconds of gate 1 during the commutation period to the reset volt-seconds of gate 2 during the normal conduction period. Finally

$$\frac{R_c}{R_c+R_b}=\frac{R_c}{R_c+R_f}\left(1-\frac{4\theta_1}{3Q}-\frac{8QR_1}{\theta_1R_c}\right) \qquad (29)$$

Solving

$$R_c=\frac{\left(1-\frac{4\theta_1}{3Q}-\frac{8QR_1}{\theta_1R_c}\right)R_b-R_f}{\frac{4\theta_1}{3Q}+\frac{8QR_1}{\theta_1R_c}} \qquad (30)$$

In general, R_f is negligible with respect to the R_b term, and equation 30 is approximately

$$R_c=\left(\frac{3Q}{4\theta_1}-1\right)R_b-18\frac{Q^2R_1}{\theta_1^2(3Q-4\theta_1)};\ 3Q>4\theta_1 \qquad (31)$$

The R_b term is quite large with respect to the R_1 term for $3Q$, more than 1 per cent greater than $4\theta_1$, and equation 31 simplifies to

$$R_c=\left(\frac{3Q}{4\theta_1}-1\right)R_b;\ 3Q>4.04\theta_1 \qquad (32)$$

To derive equation 29, the assumption has been made for

$$2e-i_2R_f=2e(1-\gamma_1) \text{ and } 2e-i_LR_f=2e(1-\gamma_2) \qquad (33)$$

that

$$1-\gamma_1\backsimeq 1-\gamma_2 \qquad (34)$$

Since the forward rectifier voltage drop is relatively small compared with $2e$ and the difference in equation 34 is smaller, the assumption will not introduce a large error.

Equation 29 has been derived for idealized core materials with zero magnetizing current, i.e., a vertical curve of magnetic induction versus magnetic intensity. This assumption is valid for small to moderate values of R_c, but breaks down completely as R_c approaches infinity. Then, the decay of the magnetizing current allows gate 2 to reset as a voltage not greater than $2e$. The error introduced by neglecting the reset effects of the magnetizing current will result in a conservative prediction of the stability border.

The load current which is divided between the two loops at θ_3 decays with a time constant $T=L/(R_L+R_c/4)$. It is shown in Appendix II that the flux change caused by the load currents adds an equal amount of set and reset flux to

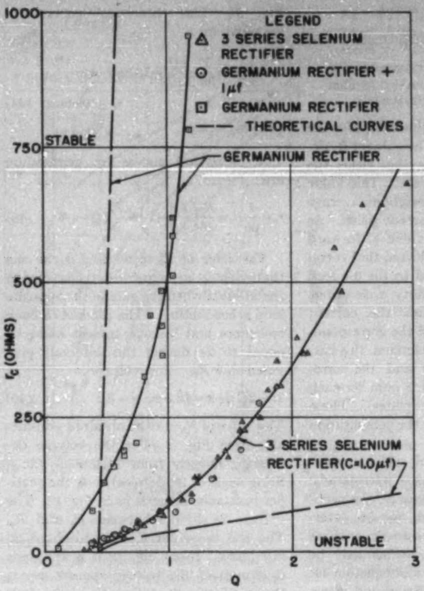

Fig. 13. Boundary of stability

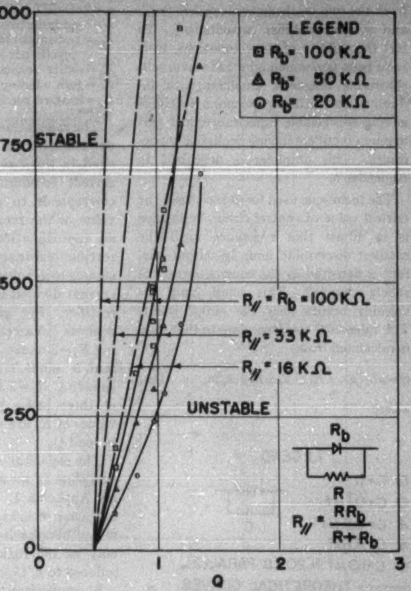

Fig. 14. Effect on stability boundary of shunting germanium rectifiers with resistors

gates 1 and 2 respectively. Consequently, this flux change does not influence the stability equation 28 because it merely adds identical terms to both sides of the equation.

Effect of Rectifier Capacitance

Next, consider the effect of rectifier capacitance. The equivalent circuit for the interval $\pi-\theta_3$ to π is shown in Fig. 12. Gate 1 is saturated and gate 2 is resetting. Gate 2 voltage in this interval (see Appendix IV) is

$$e_2=2E[\alpha(\omega t-\theta_3)-\theta_3(1-\alpha)\epsilon^{-t/\alpha\tau}+\alpha\omega\tau(1-\alpha)(1-\epsilon^{-t/\alpha\tau})] \quad (35)$$

where ωt is measured from $\pi-\theta_2$ and

$$\alpha=\frac{R_c}{R_c+R_b} \text{ and } \tau=R_b c$$

The first term is the steady-state proportional term for small firing angles; the second, the initial transient; the third, the steady-state lag with its transient term. The initial transient provides additional reset while the steady-state lag term adds set voltage. At the voltage reversal point

$$e_3(\theta/\omega)=2E(1-\alpha)[\alpha\omega\tau-(\alpha\omega\tau+\theta)\epsilon^{-\theta/\alpha\omega\tau}] \quad (36)$$

For $Q>0.5$, the experimental value of the exponent is small, and

$$e_3(\theta/\omega)=2E(1-\alpha)\frac{\theta^2}{2\alpha\omega\tau} \quad (37)$$

The gate voltage at $x=\pi$ is positive under these conditions, a result in agreement with Fig. 8.

The analysis of Appendix IV indicates that the current through the rectifier resistance (in the equivalent circuit) is perpetuated in the reverse direction beyond the voltage reversal point. At this reversal point, however, load current starts to switch to the loop under consideration, quickly reversing the rectifier current, and returns the rectifier resistance to the low, forward value. The influence of rectifier capacitance on reset flux is largely confined to the interval $\pi-\theta_3$ to π. The reset flux during this interval obtained by integration of the complete voltage equation between these limits is

$$\Delta\phi_2=\frac{2E}{N}\left\{\frac{\alpha\theta^2}{2\omega}-\theta^2\frac{\alpha}{\omega}+\alpha\omega\tau(1-\alpha)\left[\frac{\theta}{\omega}+\alpha\omega\tau(\epsilon^{-\pi/\alpha\omega\tau}-1)+\theta(1-\alpha)\times(\epsilon^{-\theta/\alpha\omega\tau}-1)\alpha\tau\right]\right\} \quad (38)$$

where θ has been written for θ_3.

For the experimental amplifier, the exponential term may be approximated to 1 per cent by its power series expansion for $R_c>360$ ohms, and

$$\Delta\theta_3=\frac{2F}{N\omega}\frac{\theta_3^3}{2}\left(1-\frac{2}{3}\frac{1-\alpha}{\alpha\omega\tau}\theta_3\right) \quad (39)$$

Performing the flux balance as before

$$R_c=\frac{R_b-R_f/\theta}{\alpha\omega\tau}Q \quad (40)$$

The R_f term is generally negligible with respect to the R_b term, and the equation becomes

$$R_c=\frac{R_b}{2\omega\tau}Q=\frac{1}{2\omega C}Q=\frac{n}{2\omega C_1}Q \quad (41)$$

where

n = number of selenium rectifier plates in series
C_1 = capacitance per plate

For the special case of $R_c=\alpha=0$, equation 38 reduces to $\Delta\phi_2=0$, and, for this case

$$R_c=0;\ Q=\frac{4}{3}\theta_1 \quad (42)$$

Experimental Determination of the Stability Boundary

In the preceding sections, equations for the stability region have been derived from the two mathematical models (with and without rectifier capacitance). To test the validity of these equations, tests have been performed on a full-wave, self-saturating magnetic amplifier with inductive load utilizing selenium rectifiers having appreciable capacitance, and germanium rectifiers having negligible capacitance. This amplifier is described in Appendix I.

The technique used for determining the critical value of control-circuit resistance is to adjust that resistance until the smallest discernible jump in output current is detected as the control current is slowly changed. This small jump invariably occurs near the cutoff point. The value of Q corresponding to that load is calculated from

$$Q=\omega L/(R_{ac}+R_{L}+R_f+R_s+R_g) \qquad (43)$$

where

$\omega=2\pi f=377$ radians per second
L = load inductance
R_{ac} = resistance of load inductance at 60 cycles per second
R_s = source resistance = 0.05 ohm
R_g = gate winding resistance = 0.78 ohm
R_f = forward rectifier resistance

The calculation is routine except for the determination of R_f. The value of R_f desired in this case is one that yields the correct commutation time. This value corresponds to some weighted average value of the rectifier current pulse. As an approximation, the value of forward rectifier resistance is selected that corresponds to a current equal to the d-c load current divided by the duty cycle of one rectifier. For germanium, this current is about 0.5 ampere, and the corresponding $R_f=2$ ohms. For selenium, this current is about 1 ampere and the corresponding $R_f=1$ ohm (1/3 ohm for each of three series rectifier plates). These values of R_f are used in the computation of load Q.

The capacitance of each selenium rectifier plate is measured as 3 microfarads; see Appendix I. Fortunately, the rectifier time constant need not be determined because it enters into the analysis only as the ratio R_b/τ, which may be reduced to n/C_1, as shown in equation 41.

A comparison of predicted and measured system performance is shown in Fig. 13. The theoretical curves for selenium are

$$r_c=\frac{1}{36}R_c=\frac{1}{36}\,\frac{nQ}{2\omega C_1}=12.3nQ\text{ ohms};\qquad r_c\geq 10\text{ ohms} \qquad (44)$$

$$Q=4/9;\quad r_c=0$$

The theoretical curves for germanium are

$$r_c=\frac{1}{36}R_c=\frac{R_b}{36}\left(\frac{3}{4}\,\frac{\theta}{\theta}-1\right)=\frac{R_b}{16}(Q-4/9) \qquad (45)$$

The value of R_b to be used is the one that yields the actual reset flux during the interval when the gate in the opposite loop is conducting. The product of back resistance and leakage current must be equal to $2e$ during this interval, provided $R_b \gg R_c$. This voltage is

$$2e=2E\sin x=42.5\sin x=R_b i \qquad (46)$$

The value of R_b may be obtained graphically from Fig. 7. For the voltage decreasing linearly from 14.4 volts (at a firing angle of 20 degrees) to 0, the rectifier resistance behaves as in Fig. 12. The voltage $2e$ divides between R_b and R_c. The test range for R_c runs to about 20 kilo-ohms. From Fig. 12 it is apparent that most of the voltage appears across the rectifier in the interval 0 to t'. It is reasonable, then, to use an average value of R_b in this interval (10,000 ohms) as a first approximation. During the interval t' to θ/ω, nearly all the voltage ap-

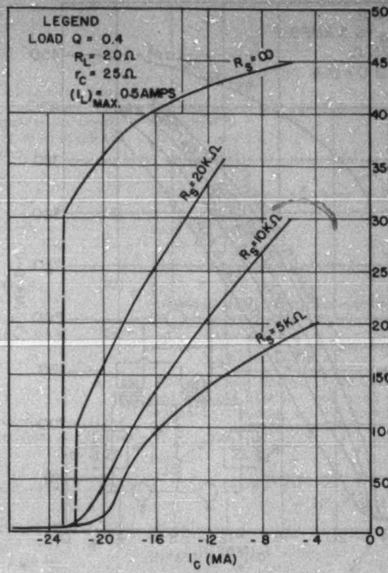

Fig. 18 (right). Effect on transfer curves of shunting germanium rectifiers with resistors R_s

pears across the core and adds reset volt-seconds. The voltage in this interval is quite low, and the additional reset flux which is a conservative influence in the predicted stability boundary will be neglected.

With this value of R_b, the theoretical equation for the case with germanium rectifiers becomes

$$r_c = 6{,}250(Q - 0.44) \tag{47}$$

Equation 47 indicates stability for $Q > 0.44$. Fig. 13 shows the tendency of the amplifier to behave in this manner. The predicted boundary for this case is on the conservative side.

With selenium rectifiers, the rectifier capacitance dominates the system and provides a greater region of stable operation. In the range investigated, there is always a stable operating point for any value of Q for a sufficiently large r_c. The predicted stability region for this case is not on the conservative side.

Effect of Rectifier Shunting

To verify the form of the analytical equations, a series of stability tests on the amplifier using shunted germanium rectifiers was performed. Fig. 14 shows the effect of shunting the rectifiers with resistors, which modifies the value of R_b in the equation. It is seen that the variation in the stability boundary behaves in the predicted manner and that the agreement between theory and experiment improves as the shunting resistor becomes smaller. Resistance shunts not only improve stability but also minimize the nonlinearity and environmental effects of the rectifiers.

Fig. 15 shows the effect of shunting the germanium rectifiers with capacitors. The analytical expression involving C now applies, and the boundary of stability does behave in the predicted manner. The theory also predicts that back rectifier resistance has negligible effect on the stability boundary within the limits of the simplifying assumptions when rectifier capacitance is appreciable. The dotted curve in Fig. 15 is for selenium rectifiers having 1-microfarad capacitance. It does correspond closely with the 1-microfarad shunting-capacitor curve for germanium even though the back resistance of germanium is many times that of selenium.

An unstable amplifier may be stabilized by shunting the rectifiers by resistance, capacitance, or both. A series of transfer curves is presented in Fig. 16, showing the stabilizing effect of shunting selenium rectifiers with resistors. Fig. 17 shows the same effect using capacitors to shunt selenium rectifiers. Figs. 18 and 19 show the same effects on the transfer curves for an amplifier employing germanium rectifiers.

Discussion of Results

No attempt was made in the analysis to include the effects of magnetizing current on stability, although a qualitative discussion of some of these effects is presented. The result of the omission is a conservative prediction of the stability boundary. A further simplification introduced in the analysis is the assumption of a constant value for back rectifier resistance. For a rectifier without appreciable capacitance, this back resistance is a primary factor in the determination of the stability boundary. The fact that this back resistance is far from constant in the regions in which its value is a key factor is a strong recommendation for its more accurate representation in future analyses.

The value of $\theta_f = 20$ degrees is used throughout the calculation for the stability borders, a value based on experimental observation and measurement. Any convenient firing angle could have been used as the maximum stable angle in the analysis but it was noted that output current was completely insignificant for angles less than 20 degrees. Although an amplifier may have an unstable jump[1] for firing angles less than 20 degrees, the results are of little practical importance unless the firing angle exceeds 20 degrees.

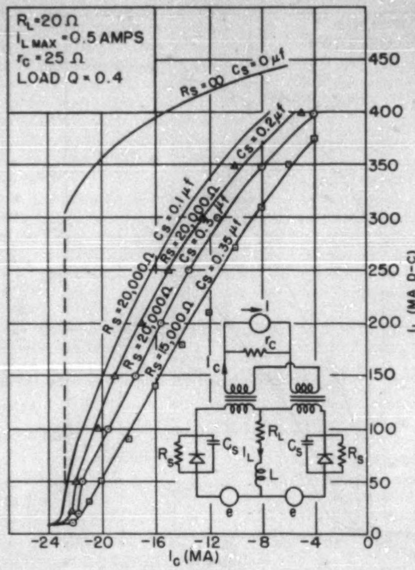

Fig. 19 (left). Effect on transfer curves of shunting germanium rectifiers with parallel resistance and capacitance

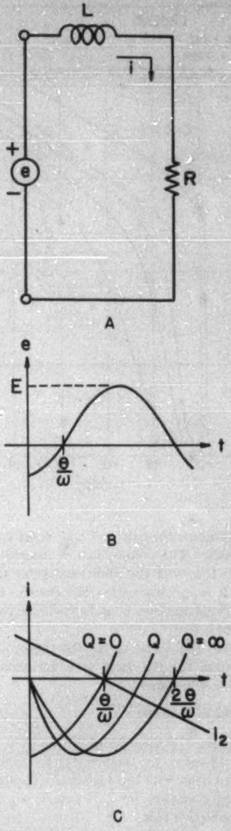

Fig. 20 (right). Equivalent circuit and wave forms for the determination of the commutation period

This value of 20 degrees, then, represents a lower limit on the small-angle analysis.

Within the framework of these approximations and the idealization of the magnetic characteristics, the boundary of stability for the full-wave, self-saturating magnetic amplifier with inductive load has been derived. For the amplifier with selenium rectifiers, (appreciable rectifier capacitance) the stability boundary is given by

$$R_c = \frac{Q}{2\omega C} \qquad (48)$$

For germanium rectifiers (negligible rectifier capacitance)

$$R_c = R_b\left(\frac{3Q}{4\theta_f} - 1\right) \qquad (49)$$

The analysis is not accurate enough to justify additional terms in equations 48 and 49.

It may be deduced from equation 49 that, for an amplifier having R_c slightly less than the critical value, θ_f and the corresponding output current will increase only to the stable value of θ_f calculable from equation 49. The circuit is not self-regenerating in that full output, i.e., $\theta_f = 180$ degrees, is not achieved for any R_c less than the critical one. This observation is confirmed experimentally. The amount of unstable jump in output may be controlled by adjusting R_c. The same behavior is exhibited by the amplifier with selenium rectifiers, although equation 48 does not predict this effect.

A further check upon the validity of the form of equation 49 has been obtained by increasing the a-c supply voltage $e = E \sin \omega t$. Equation 49 predicts that large values of the initial firing angle θ_f improve the stability border by allowing smaller values of R_c. If the supply voltage is increased, the gates are no longer able to absorb the full half-cycle of voltage and, consequently, they must fire before the end of each half-cycle, regardless of the amount of bias. As the voltage is increased, θ_f must increase. An experimental check of the critical R_c with constant R_L and Q has confirmed the predicted decrease in critical R_c with increasing voltage.

This paper describes several methods of obtaining high stable gain with inductive loading when negative feedback is introduced. Examples of the influence of negative feedback obtained by rectifier shunting are illustrated in Figs. 14 through 19. An incidental advantage of negative feedback by rectifier shunting is a relative independence of amplifier performance on varying rectifier characteristics.

Summary

This paper may be considered as a first deviation from the case of idealized components to predict the performance of magnetic amplifiers. Although the idealization of components is convenient for determining the gross aspects of magnetic amplifier performance, it has been shown here and elsewhere that the departures from the ideal determine performance in many instances.[7,8] Intimate knowledge of the effects of these departures will enable the designer to minimize them in some cases and utilize them to advantage in others.

For the full-wave, self-saturating magnetic amplifier, a relation between the constraint of the control circuit and the reactive loading has been developed. The effects of the rectifier imperfections such as forward resistance, back resistance, and back capacitance have been introduced. The imperfections of the gate such as hystereses, eddy current, magnetizing current, leakage reactance, and winding capacitance, at best, have been introduced only in a qualitative fashion. In a recent paper[9] it has been shown that the rate of flux change within the magnetic amplifier gate is a function of many factors including core material and core material strip thickness. It is thought that, even at the low frequencies (60 cycles per second) at which the tests were conducted, better theoretical-experimental correlation would have been obtained if gate imperfections had been included. At higher frequencies, the deviations from ideal gate characteristic are such that their effects on the amplifier performance would become increasingly important. Further detailed studies of magnetic amplifier performance, particularly at higher frequencies, could profitably explore these characteristics of the gate along with a more detailed analysis of the dynamic back resistance of the rectifier.

Appendix I. Description of Experimental Amplifier

The Deltamax test cores are tape-wound toroids, Arnold Engineering Company, case no. *4180-D1*. Core size: outside diameter = 3.00 inches, inside diameter = 2.50 inches, height $h=0.50$ inch. Tape size $t=0.001$ inch. Gate winding = 600 turns and 0.78 ohm each, and control winding = 100 turns and 0.66 ohm each.

The selenium rectifiers are International Rectifier Corporation type-*E* rated at 3.3 amperes d-c. They have 3-microfarad capacity per plate as measured on a *GR* bridge at 1,000 cycles per second. The germanium rectifiers are General Electric Company type-*G10*. The d-c resistance characteristics of both rectifiers are shown in Fig. 7.

Appendix II. Computation of Load Current

The interval beyond the voltage reversal point during which load current continues to flow is known as the commutation period. Such an interval exists for an inductive load in a full-wave, self-saturating magnetic amplifier. For the idealized system containing perfect rectifiers and negligible magnetizing current, the commutation period may be evaluated.

Consider the series *RL* circuit having an impressed voltage; see Fig. 20(A) and (B)

$$e=0;\ t<0$$

$$e=E\sin(\omega t-\theta);\ t>0 \qquad (50)$$

The loop equation is

$$e=L\frac{di}{dt}+Ri;\ i(0)=0 \qquad (51)$$

First consider the case in which no load current switches from one loop to the other during the complete commutation period. To find the time t_1 (L, R, θ) at which the current first returns to zero, let

$$\omega t-\theta=x;\ Q=1/p=\omega L/R;$$

$$\frac{d(\ )}{dt}=\frac{d(\ )}{dx}\frac{dx}{dt}=\omega\frac{d(\ )}{dx} \qquad (52)$$

then

$$E\sin x=\omega L\frac{di}{dx}+Ri;\ i(-\theta)=0 \qquad (53)$$

$$\frac{E}{R}\sin x=Q\frac{di}{dt}+i=\frac{E}{Z}\sqrt{1+Q^2}\sin x \qquad (54)$$

where

$$Z^2=R^2+\omega^2L^2=R^2(1+Q^2)$$

Solutions of $i(x)$ for three values of Q are shown in Fig. 20(C) for constant Z. Equation 54 may be written

$$\frac{di}{dx}+pi=\frac{E}{Z}\sqrt{1+p^2}\sin x;\ i(-\theta)=0 \qquad (55)$$

The solution to equation 55 is

$$i(x)=\frac{E}{\sqrt{1+p^2}}[\epsilon^{-p(x+\theta)}(p\sin\theta+\cos\theta)+p\sin x-\cos x] \qquad (56)$$

as can be verified by substituting into the differential equation and the initial condition equation.

For $x=y$, the current is again zero, and the equation for y is

$$\epsilon^{-p(y+\theta)}(p\sin\theta+\cos\theta)=\cos y-p\sin y \qquad (57)$$

Rearranging

$$\epsilon^{-p\theta}(p\sin\theta+\cos\theta)=\epsilon^{+py}(\cos y-p\sin y) \qquad (58)$$

The desired solution to this equation is the smallest value of time $t_1=y/\omega$ for which it is satisfied.

For the special case of small commutation periods and large circuit Q, equation 58 may be written as a finite power series expansion of the component parts as follows

$$\left(1-p\theta+\frac{1}{2}p^2\theta^2-\frac{1}{6}p^3\theta^3+\frac{1}{24}p^4\theta^4-\ldots\right)\times\left(p\theta-\frac{1}{6}p\theta^3+\frac{1}{120}p\theta^5-\ldots+1-\frac{1}{2}\theta^2+\frac{1}{24}\theta^4-\ldots\right)=\left(1+py+\frac{1}{2}p^2y^2+\frac{1}{6}p^3y^3+\frac{1}{24}p^4\theta^4+\ldots\right)\left(1-\frac{1}{2}y^2+\frac{1}{24}y^4-\ldots-py+\frac{1}{6}py^3-\frac{1}{120}py^5+\ldots\right) \qquad (59)$$

Simplifying equation 59, and keeping terms through y^4 yields

$$y^2=\theta^2\frac{1-\frac{2}{3}p\theta+\frac{1}{12}\theta^2(3p^2-1)}{1+\frac{2}{3}py+\frac{1}{12}y^2(3p^2-1)} \qquad (60)$$

The solution of this equation accurate to terms in θ^2 is

$$y=\theta\left(1-\frac{2}{3}p\theta\right) \qquad (61)$$

Iterating equation 60 yields

$$y=\theta\left(1-\frac{2}{3}p\theta+\frac{4}{9}p^2\theta^2\right) \qquad (62)$$

good for terms including θ^3. For

$$\frac{4}{9}p^2\theta^2<0.02\ (\text{i.e., }\theta^\circ<12Q);\ \omega t_1=y=\theta\times\left(1-\frac{2}{3}p\theta\right)\pm2\text{ per cent} \qquad (63)$$

Next consider the case in which load current switches from the loop under consideration to the other in the amount $i_2=2e/R_c$. To find the time t_2 (L, R, R_c) at which $i_2=i/2$, the equation of condition 57 becomes

$$\epsilon^{-p\theta}(p\sin\theta+\cos\theta)=\epsilon^{py}(\cos y-(p-d)\sin y) \qquad (64)$$

where

$$d=4Z\sqrt{1+p^2}/R_c$$

For the special case of small commutation periods, equation 64 may be expanded in a finite power series as before, and the commutation angle becomes

$$y=\theta\left(1-\frac{2}{3}p\theta-\frac{4R}{p\theta R_c}\right)\pm2\text{ per cent};\quad p\theta<0.2,\ R_c>500R \qquad (65)$$

Appendix III. Circuit Analysis: Both Loops Conducting and Neither Gate Saturated

This circuit configuration may occur in the case of the full-wave, self-saturating magnetic amplifier with inductive load, provided that the two loop currents are equal (and are half the load current) and the control current is equal to the negative of either loop current times a; see Fig. 1. Then

$$e=e_L+e_1 \qquad -r_ci_c=a(e_1+e_2)$$

$$-e=e_L+e_2 \qquad e_L=R_Li_L+L\frac{di_L}{dt} \qquad (66)$$

Let

$$i=i_1=i_2=\frac{1}{2}i_L=-ai_c \qquad (67)$$

Then

$$e_1+e_2=-2e_L=r_ci/a^2\text{ and }e_L=-i_Lr_c/4a^2 \qquad (68)$$

Also

$$L\frac{di_L}{dt}+\left(R_L+\frac{r_c}{4a^2}\right)i_L=0 \qquad (69)$$

The solution of equation 69 is

$$i_L(t)=i_L(0)\epsilon^{-t/T}$$

where

$$T=L/(R_L+r_c/4a^2) \tag{70}$$

and $i_L(0)$ is the current at $t=0$. In addition, gate 1 sets and gate 2 resets at an increased voltage

$$e_1=-e_2=e+i_Lr_c/4a^2=e+i_L(0)\frac{r_c}{4a^2}\epsilon^{-t/T} \tag{71}$$

The additional set or reset flux from the increased voltage over an interval 0 to π/ω is

$$\Delta\phi=\frac{1}{N}\int_0^{\pi/\omega}\frac{r^2}{4a^2}\epsilon^{-t/T}dt\approx\frac{Tr_c}{4a^2N}i_L(0) \text{ for } T\ll\pi/\omega \tag{72}$$

$$\Delta\phi\approx2\phi_s\frac{\omega Tr_c}{8Ea^2}i_L(0)$$

In any practical amplifier $T\approx4a^2L/r_c$, and equation 72 becomes

$$\Delta\phi\approx2\phi_s\frac{\omega iL_L(0)}{2E} \tag{73}$$

The time $t=0$ in this analysis corresponds to the time t_2 in Fig. 6. For the condition of impending instability, the firing angle $\theta_f=20$ degrees. The current cannot exceed $(2Ea^2/r_c)\sin\theta_f$. Then

$$\Delta\phi\approx2\phi_s\frac{\omega L}{27r_c} \tag{74}$$

For the range of experimental data, $\Delta\phi/2\phi_s$ ranges from 0.1 to 2 per cent.

The condition of impending instability is defined by equal set and reset flux over the half-cycle. The increment of flux change adds equal amounts of set and reset flux to the two gates. The magnitude of the additional flux change is small so that the principle of superposition may be applied. Consequently, the stability effects on both cores cancel and there is no resulting effect on stability.

Appendix IV. Effect of Rectifier Capacitance on Reset Flux

In a full-wave, self-saturating magnetic amplifier with inductive load, the load current flows in a series of pulses, each pulse starting at the firing angle and continuing through the voltage reversal point to the end of the commutation period. During this interval, rectifier capacitance has its greatest influence on reset flux. Not only does it modify the reset voltage of the gate but it also tends to keep the rectifier in a region of high resistance by perpetuating the rectifier current in the negative direction beyond the voltage reversal point. At this reversal point, however, some of the load current switches to the loop being considered and causes the rectifier resistance to drop to a low value only slightly beyond the reversal point.

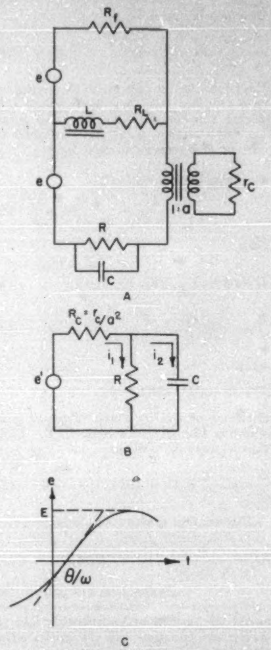

Fig. 21. Equivalent circuits and voltage wave forms for the determination of the effect on reset flux of rectifier capacitance during the flow of load current

To evaluate these effects on the reset flux, the equivalent circuit of Fig. 21(A) and its approximation (B) must be considered. The voltage impressed in this circuit, which (ideally) is double reset voltage, see Fig. 21(C), is

$$e'=e+\frac{Z_L}{Z_L+R_f}e=2e\left(1-\frac{1}{2}\,\frac{R_f}{R_f+Z_L}\right)=2e(1-\gamma) \tag{75}$$

In the analysis, γ is neglected; see equation 34. The voltage e is

$$e=0;\ t<0$$

$$e=E\sin(\omega t-\theta);\ t>0 \tag{76}$$

For $\theta\ll\pi$, the voltage e may be approximated, dotted line of Fig. 21(C), by

$$e=E(\omega t-\theta);\ 0<t<2\omega/\theta \tag{77}$$

The gate voltage is

$$e_{R_c}=2e[\alpha(\omega t-\theta)-\theta(1-\alpha)\epsilon^{-t/\alpha\tau}+\alpha\omega\tau(1-\alpha)(1-\epsilon^{-t/\alpha\tau})] \tag{78}$$

In the interval 0 to θ/ω, the flux change becomes

$$\Delta\phi=\frac{1}{N}\int_0^{\theta/\omega}e_{R_c}dt=\frac{2E}{N}\left[\left(\frac{\alpha\theta^2}{2\omega}-\frac{\alpha\theta^2}{\omega}\right)+\alpha\omega\tau(1-\alpha)\left(\frac{\theta}{\omega}+\alpha\tau\epsilon^{-\theta/\alpha\omega\tau}-1\right)+\theta(1-\alpha)\alpha\tau(\epsilon^{-\theta/\alpha\omega\tau}-1)\right] \tag{79}$$

For $\theta/\alpha\omega\tau$ small, the exponentials may be approximated by finite power series and through terms in θ^3. Then, equation 79 becomes

$$\Delta\phi=-\frac{2E}{N\omega}\,\frac{\theta^2}{2}\left(1-\frac{2}{3}\,\frac{1-\alpha}{\alpha\omega\tau}\theta\right) \tag{80}$$

The Ring Modulator as a Polarized Rectifier

A. J. HERMONT
MEMBER AIEE

Synopsis: The performance of the ring modulator as a phase-sensitive rectifier is described qualitatively. Under the assumption of idealized conditions, and with the use of the analytical approach originally developed for the ring modulator, the polarized rectifier is described quantitatively, both for steady state and transient state. The analytical findings are checked experimentally. A differential polarized rectifier functioning as a true null detector is also discussed.

WHENEVER it becomes necessary to establish the absolute steady-state equality between two electrical phasors, a null-indicating device, or a null detector, must be used. Many such devices are in use to indicate the balance condition of bridges and, in a broader field, to permit the absolute measurement of phasor relationships.

Attention was focused early on the ring modulator, so successfully used in carrier communication, for, if instead of employing two different frequencies, i.e., the signal and carrier frequencies, the two are permitted to merge into a single measuring frequency, a new and powerful tool, the polarized rectifier, is obtained. Although the device has been previously described in the literature,[1,2] it is felt that it has been neither comprehensively treated nor given the recognition it deserves as one of great inherent usefulness. It is therefore proposed to cover this subject rather thoroughly in the following discussion.

Qualitative Aspects

The arrangement illustrated in Fig. 1(A) is diagrammatically identical to the ring modulator, although it differs functionally from the ring modulator arrangement. Fundamentally, four nonlinear resistance elements (1-2, 2-3, 3-4, 4-1), either of the vacuum-tube or the semiconductor type, are connected in series forming a "ring." (In the following, only the semiconductor type will be considered. All work was done with the Western Electric type-*D-98914* cuprous-oxide–copper varistor.) During the positive 1/2-cycle of signal e_s'' the resistance of one pair of elements is substantially reduced; during the negative 1/2-cycle, that of the other pair undergoes such a reduction, the medium producing these (exactly synchronous) reductions being an auxiliary potential, the polarizing potential e_p'', whose frequency is identically the same as that of the signal and whose amplitude is substantially in excess of that of the signal. In what manner rectification takes place will become apparent upon study of current flow for each 1/2-cycle, identified by solid and dashed arrows. Polarizing energy coupled into the circuit via an isolation transformer produces current $2i_p$ (solid), which splits at 5 into two equal components i_p. It will be assumed, for simplicity, that the resistance of an element in the blocking direction is infinite and that the characteristics of the elements are identical among each other. One component i_p thus greatly reduces the resistance of element 1-2, the other one that of 3-4: the pair of elements 1-2 and 3-4 are "unlocked" by the polarizing energy while the pair 2-3 and 4-1 becomes "forbidden" for energy transfer. Signal energy, likewise coupled by means of an isolation transformer, establishes current i_s (solid) freely flowing through 1-2, splitting into components i_q and i_r, recombining into i_s, and freely continuing through the unlocked element 4-3. For the next 1/2-cycle, polarizing current $2i_p$ (dashed) unlocks elements 2-3 and 4-1, forbidding passage through the pair 1-2 and 3-4. Signal energy, which has also undergone a synchronous phase reversal, establishes current i_s (dashed) flowing through 3-2, splitting into i_q and i_r and continuing through 4-1. It is at once realized that the direction of i_r and i_q remains invariant for either 1/2-cycle, and that hence the phenomenon of rectification takes place. A little thought will further reveal, that, if the polarity of e_p' is maintained while that of e_s' is reversed, the direction of i_r will likewise reverse: the phenomenon of passage through zero for phase reversal is guaranteed. Further study of the diagram indicates that for $e_s'=0$, no current flows through r (which represents the branch in which a d-c galvanometer

is placed), since polarizing energy is exactly balanced out from that branch: the phenomenon of zero output for zero input also exists. The polarized rectifier indicated in Fig. 1(B) has the same desirable properties as the one illustrated in Fig. 1(A); however, sufficient elimination of polarizing energy from the galvanometer is not possible, especially if high sensitivity is demanded.

This qualitative discussion exhibits the fundamental properties of this type of detector and puts the whole a-c null proposition on the reliable basis of a d-c null device. But no indication is provided concerning the operation of the detector as a function of phase displacement between signal and polarizing potentials (except the 2π displacement), no hint is given regarding selectivity, no information referring to sensitivity is contained in this discussion. It takes a mathematical approach to settle these questions.

Analytical Aspects

The expression for the galvanometer deflection δ in terms of the harmonic signal strength E_{sm} and other physical factors has been derived in the Appendix. See equation 26.

The result may be summarized in terms of the following statements:

> For idealized semiconductor specifications, the d-c output current is strictly proportional to the real component of the signal voltage with respect to the polarizing voltage. If a voltage of different frequency is superimposed on the signal, it can contribute to the d-c output current only in so far as it is an exact odd harmonic of the signal frequency: in that case the additional contribution to the output is proportional to the real component of the signal voltage and inversely proportional to the order of the harmonic; the contributions attributable to the harmonics are either aiding or bucking the contribution attributable to the fundamental.
>
> All this reveals the paramount property that the output is not only sensitive to the real component of the signal phasor, but is also discriminative in favor of the signal frequency, so that unwanted energy is largely rejected. It is also seen very clearly that a null will obtain not only for the condition of zero input signal amplitude but also for a quadrature signal phase (with respect to the polarizing potential) and one must be on guard for this latter "fake" null.
>
> As to the a-c output, it has already been mentioned that the fundamental frequency is completely balanced out as far as polarizing energy is concerned. In the light of the analysis this statement becomes more precise. If, for simplicity, the uncommutated signal current is assumed to be $i_{R_{NC}} = I_{R_m} \cos m\omega t$, then the contribution to the a-c output current attributable to the nth harmonic of the commutating voltage is, by equation 7

$$i_{R_{mn_c}}=\frac{4}{\pi}\,\frac{I_{R_m}}{n}\cos m\omega t\cos n\omega t$$
$$=\frac{2}{\pi}\,\frac{I_{R_m}}{n}\{\cos(m-n)\omega t+\cos(m+n)\omega t\}\qquad(1)$$

If the signal frequency is exactly identical to the polarizing frequency, then $m=n=1$ and

$$i_{R_c}=\frac{2}{\pi}I_R(1+\cos 2\omega t)\qquad(2)$$

so that a second harmonic (as well as a d-c component) is expected. If a second harmonic is present in the signal, i.e., $m=2n$, a fundamental component, however, will result, in addition to a third-harmonic component as

$$i_{R_{mn_c}}=\frac{2}{\pi}I_{R_m}(\cos\omega t+\cos 3\omega t)\qquad(3)$$

These considerations are incorporated in the following statement: If the signal is distorted the output current contains harmonics and may contain the fundamental for the special case of a second harmonic distortion; moreover, as $m\rightarrow n$, slow beat frequencies will appear. It will be the function of the indicating device, i.e., the device capable of energy storage, to suppress these a-c components as much as possible.

The transient response is less favorable. According to equation 31 and the remark following it, every exponentially decaying step function is accompanied by a decaying train of square waves. If the polarizing frequency is low, the wave train will cause a bothersome fluctuation of the galvanometer and, unfortunately, no remedy for this defect exists.

Equation 26 represents an important result, the experimental verification of which it is proposed to study next. This will contribute to a full appreciation of the complexities involved and will shed some light on the validity of the idealizations of the functioning of the device used in the analysis.

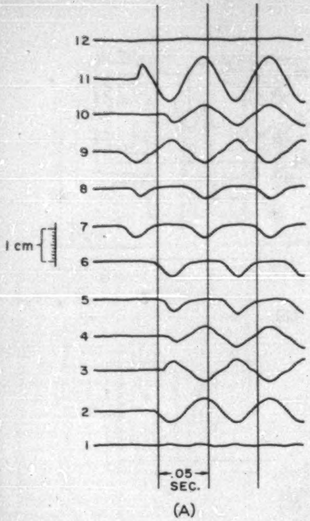
Experimental and Quantitative Aspects

Accordingly, Fig. 2, a special circuit of the general type under discussion, with suitable components for recording by means of a multichannel oscillograph has been developed. The locations of the twelve galvanometer elements (the resistance of each is about 20 ohms) are indicated by numerals 1 to 12, which correspond to the trace numbers on the oscillograms.

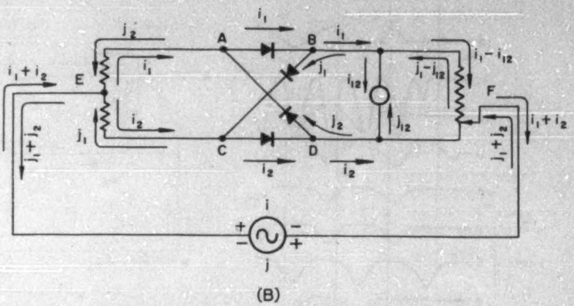
Fig. 3 is a tracing from an oscillogram for exact suppression of polarizing energy (frequency 14.3 cycles per second) from the output (trace 11) with zero-applied signal (trace 12). The polarizing voltage existing at the secondary of the polarizing transformer is 0.217-volt peak and is maintained throughout the tests. The d-c calibrations for the galvanometers are indicated in Fig. 2.

No fundamental is visible on trace 11 which does, however, indicate higher odd harmonics. Traces 5 and 6 show that flow of conduction currents through elements AB and CD occurs simultaneously, while conduction current flows through elements BC and DA simultaneously for the other 1/2-cycle of the polarizing voltage (traces 7 and 8 respectively). Phase reversals on traces 3 and 4, and on 9 and 10, result from the polarizing current flowing in opposite directions through resistors p_1 and p_2, and the same is true for the currents through resistors q_1 and q_2. Fundamental balance on trace 11 results for $p_1=248$ ohms and $q_1=229$ ohms, i.e., for a near-center position of the controls.

The reason for the appearance of a third harmonic on traces 3, 4, 9, 10, and 11 is fairly obvious. At all times the polarizing potential is equal to the sum of the voltage drops in p_1 and q_1, for example, and in semiconductor AB. If the polarizing potential is assumed purely sinusoidal and if the voltage across the semiconductor of the shape illustrated in Fig. 4 is subtracted from it, a voltage shape precisely as indicated by traces 3, 4, 9, and 10 results. Moreover, if the funda-



(A)



(B)

mental is balanced out, the shape indicated on trace 11 obtains.

Next, it is assumed that, still without feeding signal energy to the device, the p-balance is disturbed. Fig. 5(A) is an oscillogram for a drastic change: $p_1=498$ ohms, $p_2=0$. The result is not considered obvious, and it requires at least a qualitative analysis. A simplified network diagram is shown in Fig. 5(B), in which the polarizing energy for one 1/2-cycle feeds current i, and for the next 1/2-cycle, current j. The q-balance is shown at its center position, while the p-balance is upset as mentioned above. Thus, considering all ring elements to be identical, $i_2>i_1$, no matter how far the tap-point E is moved toward the bottom. For example, from Fig. 5(A), and with the use of the calibrations shown in Fig- 2, the maximum values of these currents are: $i_2=\delta_6\times\sigma_6=7.5\times41.7\times10^{-6}=313\times10^{-6}$ ampere and $i_1=\delta_5\times\sigma_5=5\times42.3\times10^{-6}=212\times10^{-6}$ ampere. For simplicity, it is assumed that branches AD and CB are totally blocking, so that currents i_2 and i_1 issue from points D and B respectively. Referring now, to Fig. 5(C), it is obvious that the current in the galvanometer branch becomes $i_{12}=i_2'-i_1'$ (the currents i_2 and i_1 flowing simultaneously) and, since $i_2'>i_1'$, the direction of i_{12} (Fig. 5(B)) is from D to B. For the j 1/2-cycle, the distribution of the currents is as shown, with $j_2>j_1$. Thus, the current in the galvanometer branch becomes $j_{12}=j_2'-j_1'$, in the direction of j_2', i.e., again in the direction from D to B. Thus a second-harmonic current is formed in the galvanometer branch, and this current possesses an average value. This is clearly shown on trace 11. If the p-unbalance were changed in the opposite direction, the polarity of the d-c component would reverse. These experiments indicate that the d-c component, along with the second-harmonic component, may be completely "zeroed" by an adjustment of the p-potentiometer: for then $i_2=i_1$ and $j_2=j_1$ and points B and D are at the same potential. This type of balance is loosely called the d-c polarizing balance (Fig. 2).

Fig. 6. A-c polarizing balance. A—Experimental results. B—Explanatory schematic

When next the q-balance is disturbed, no visible d-c component develops on trace 11, but fundamental frequency is evidenced, as seen from Fig. 6(A). The situation is illustrated by the schematic of Fig. 6(B), which shows the q-potentiometer drastically unbalanced (tap-off point F at bottom). Here $i_2>i_1$, and i_2 flows from D back to the generator; i_1 sends a component i_{12} through the galvanometer branch. For the j 1/2-cycle, j_2 flows directly to D while j_1 sends a component j_{12} in the opposite direction through the galvanometer branch; for identical elements $i_{12}=-j_{12}$. Cancellation, however, does not occur since these currents flow in time-quadrature; hence a near sine wave results. If the tap F is adjusted correctly, then $i_1=i_2$ and $j_1=j_2$, so that the voltage drop from F to B is equal to the one from F to D, and current in the galvanometer branch vanishes. This experiment teaches that the fundamental of the polarizing current may be completely zeroed by an adjustment of the q-potentiometer. This type of balance is referred to as the a-c polarizing balance (Fig. 2). Fig. 6(A) refers to $q_1=200$ ohms.

Before proceeding further, it is necessary to study the particular semiconductor arrangement more closely. Examination of equation 26 indicates that the d-c deflection produced by the polarized rectifier in response to an input voltage E_s depends on the quantities ρ_0 and g_G, which are governed by the particulars of the circuit arrangement; it also depends on other quantities irrelevant to the present discussion, and associated with the nature of the input signal itself and with the properties of the null-indicating device. But ρ_0 and g_G, by equations 16, 19, and 23 are functions of S and thus, in the last analysis, of the crucial quantities r_f and r_b by equation 17. Therefore, the question arises: what constant values should be assigned to these quantities? Of course, r_f and r_b are known to be nonlinear functions of time, but the analysis ignored this fact and assumed them to be constant. It must also be understood that the only information assumed to be available at the outset is the static current-voltage characteristic of the particular unilateral semiconductor under investigation, usually published by the manufacturer. For the Western Electric type-*D-98914* this relation is revealed for the forward 1/2-cycle and the backward 1/2-cycle by the "current" curves of Fig. 7(A), and (B) respectively. The static resistance being of no concern here, graphical differentiation of the current functions results in the dynamic-resistance functions, also shown in Fig. 7.

It should furthermore be assumed that the only information available regarding the voltage across either of the four semiconductor elements is its peak value, which is a design specification. That the voltage is not sinusoidal is illustrated by Fig. 4, which was obtained by using a d-c amplifier for the recording of the latter. It is somewhat surprising that the voltage

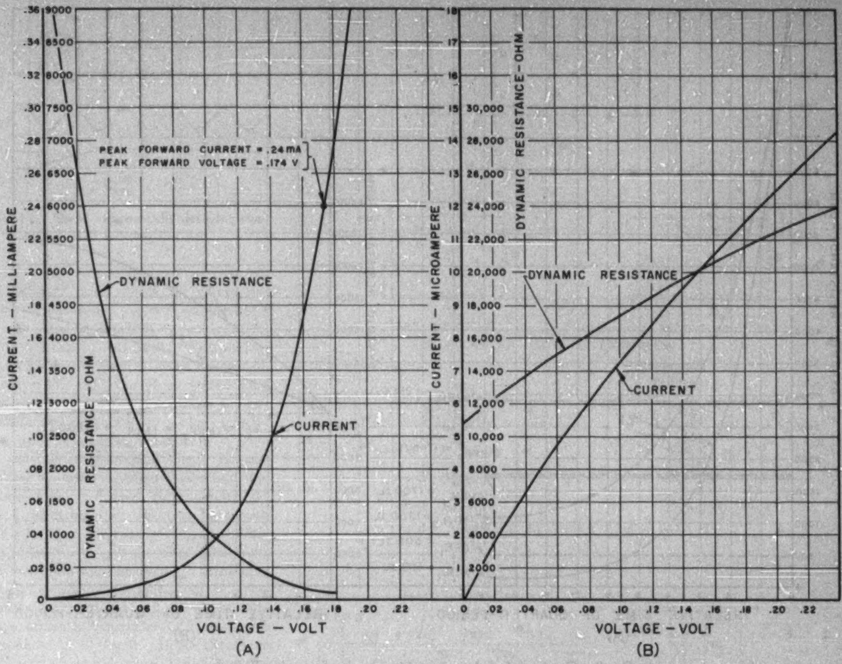


Fig. 7. Half-cycle semiconductor characteristics, Western Electric type D-98914. A—Forward. B—Backward

is so nearly sinusoidal. As an explanation of this phenomenon, it will be observed, by reference to Fig. 2, that the polarizing current I_p splits into two components i_{p_1} and i_{p_2}; i_{p_1} splits at A into i_{b_1} and i_{f_1}, while i_{p_2} splits at C into i_{b_2} and i_{f_2}, where the i_f-currents are understood to greatly exceed the i_b-currents. Assuming the potential at point D to be zero, the instantaneous potential of point A becomes $+i_{b_1}r_{b_1}$ if branch AD is considered; if branches AB and BC are considered, it becomes $+i_{f_1}r_{f_1}-i_{b_2}r_{b_2}+i_{f_2}r_{f_2}$. Thus it follows, by equating the potentials at A, that $i_{b_1}r_{b_1}+i_{b_2}r_{b_2}=i_{f_1}r_{f_1}+i_{f_2}r_{f_2}$ and, for identical elements, that

$$i_b r_b = i_f r_f \tag{4}$$

which implies that in this arrangement there exists a "constraint" on the instantaneous voltage across an element, forcing the voltage to remain invariant for either half-cycle. This is why the voltage-time distribution is so symmetrical with respect to the time axis. With this in mind and for purposes of further simplification of the problem, it is now assumed that the voltage-time distribution across an element is strictly sinusoidal.

To restate the immediate objective: It is required to find two quantities r_f and r_b, both constant over the respective half-cycle, such that when they are introduced into the proper equations, they will yield the d-c deflection produced by the polarized rectifier as demanded by equation 26. But this is manifestly contrary to the physics of the situation, since it has been shown that the dynamic resistances are by no means constant as functions of voltage and, hence, as functions of time. The simplifying assumptions made in the analysis are nevertheless justifiable, as will be subsequently shown. These assumptions, of course, were made in order to avoid the difficulties of the nonlinear mathematics involved in the problem. It should be stressed that resort to empiricism is deliberately undertaken at this point and that all claims to rigor are relinquished as is the expectancy of perfect agreement between analysis and experiment.

Returning to the conditions of the experiment, it is seen from the calibrated Fig. 4 that the peak forward current is 0.24 milliampere (ma) and the peak forward-and-backward voltage about 0.174 volt. The distribution of the forward-and-backward dynamic resistances, plotted against a relative quarter-period time scale and based on the foregoing sinusoidal voltage-time distribution, is revealed by curves 1 of Fig. 8. The minimum forward resistance is 150 ohms, the minimum backward resistance 10,800 ohms. The question is, what effective forward-and-backward resistance may be deduced from this information?

For the forward quarter-period it is felt that the minimum resistance should play a part; also that the time-average resistance should be involved. The empirical formulation is now made that the effective forward resistance shall be the geometric mean between the time-average and the minimum resistances. Accord-

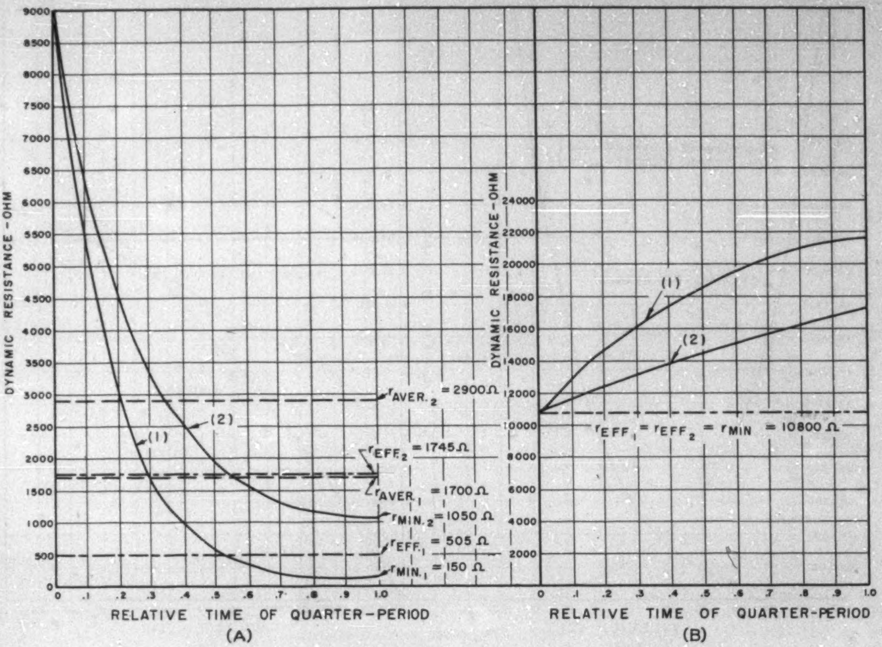

Fig. 8. Quarter-period dynamic resistance. A—Forward. B—Backward

ingly, since graphical integration of curve 1, Fig. 8(A) results in an average resistance of 1,700 ohms, the effective forward resistance becomes $r_f=505$ ohms. For the backward quarter-period, it is felt that the rise of dynamic resistance over its value at the transition between the forward-and-backward quarter-periods should be ignored; this, too, is based on empirical procedures. Accordingly, the effective backward resistance becomes $r_b=10,800$ ohms. With these values decided upon, the computation of δ from equation 26 proceeds without difficulty.

Referring to Fig. 9(A) i.e., to the case where the signal voltage is the fundamental and the phase shift is zero (or 180 degrees), equation 26 becomes $\delta=(2/\pi)(1/\sigma_G)g_G\rho_0E_s$. For the transformer indicated in Fig. 2, the experimentally determined constants are $L_1=387$ henrys, $R_1=1,800$ ohms, $R_2=52$ ohms, $\nu=7.75$. By equation 17 $S=2,335$. The fourpole resistance R_P may be computed from equation 19 if $R=2qr//2q+r=448\times 471.5/919.5=229.7$ ohms is substituted, with the result $R_P=1,145$ ohms. Thus the total load resistance R_o becomes 257.5 ohms (parallel combination of R_P, 1,000 ohms, 498 ohms).

Therefore, by equation 16 $\rho_0=9.82\times 10^{-2}$, when the frequency 13.4 cycles is given consideration. Equation 23 yields $g_G=3.72\times10^{-4}$ mho, while E_s is taken from Fig. 9(A) from the deflection of the calibrated galvanometer 12, namely $E_s=\delta_{12}\sigma_{12}26\times10^3=7\times0.85\times10^{-6}\times26\times10^3=$

Fig. 12. Polarized rectifier analysis

0.1547-volt peak. With the galvanometer sensitivity $\sigma_G=\sigma_{11}=1.27\times10^{-6}$ finally, analysis yields $\delta_A=2/\pi\times1/1.27\times10^{-6}\times3.72\times10^{-4}\times9.82\times10^{-2}\times0.1547=$ 2.84 millimeters (mm). Next, the shaded area in Fig. 9(A) was planimetered and, as an average of seven readings, the experimental deflection by means of oscillography becomes $\delta_{EO}=4.09$ mm.

Another experimental check is provided by observing the d-c deflection of a long-period sensitive galvanometer G' and adjusting the deflection by means of a decade resistor R_D (see Fig. 2). With $R_D=5{,}000$, a galvanometer deflection $\delta_{G'}=16$ mm was observed. Taking into account the coil resistance and the sensitivity indicated in Fig. 2, the direct voltage across galvanometer 11 is computed to be 3.51×10^{-6} volt. Hence the direct current through element 11 is 1.755×10^{-8} amperes and, taking into account the sensitivity of element 11, the experimentally obtained deflection by means of a long-period galvanometer becomes $\delta_{EG'}=3.815$ mm.

Fig. 9(B) illustrates a case where phase shift is involved. Directly from the oscillogram the signal voltage (trace 1) lags behind the polarizing voltage (trace 2) by 54 degrees, if trace 1 is considered recorded 180 degrees out of phase. The oscillogram trace 12 furnishes $E_s=0.1492$-volt peak; hence $E_s\cos\varphi=0.0877$-volt peak. The other quantities remaining as in the previous case, analysis furnishes $\delta_A=1.61$ mm. The oscillographic approach yields $\delta_{EO}=2.10$ mm, while the long-period galvanometer provides $\delta_{EG'}=$ 1.91 mm.

If a strong third harmonic is present in the signal, a situation revealed by Fig. 10 results. Observe that since the signal phase (trace 1) is reversed as compared to the signal in Fig. 9(A), the d-c component on trace 11 is also reversed as expected. A Fourier analysis of the signal on trace 12 was made, the results being for $m=1$, 3,5: $E_{s1}=0.148$, $\varphi_1=-9.25$ degrees; $E_{s3}=0.0151$, $\varphi_3=+77.38$ degrees; $E_{s5}=$ 0.00638, $\varphi_5=-80.37$ degrees. If for the higher harmonics the asymptotic value of $\rho_{om}=0.0983$ is used

$$\sum_{m=1}^{m\,\mathrm{odd}}\frac{E_{sm}\rho_{om}}{m}\cos\varphi_m=0.148\times9.82\times$$

$$10^{-2}\times0.9871-\frac{1}{3}\times0.0151\times9.83\times$$

$$10^{-2}\times0.2181+\frac{1}{5}\times0.00638\times9.83\times$$

$$10^{-2}\times0.1668=+0.014263$$

so that $\delta_A=2.66$ mm. The oscillogram yields $\delta_{EO}=3.84$ mm and the long period galvanometer $\delta_{EG'}=3.82$ mm.

If the results observed by means of the long-period galvanometer are considered correct, it must be concluded that the analytic results are at the most about 30 per cent lower than the true ones, i.e., they are on the conservative side.

Fig. 11 illustrates the response to an exponentially decaying step function, which is seen to be in complete accord with equation 31.

All these results are very gratifying, for they prove that the operation of the device is clearly understood and that the idealizing assumptions are justified in view of the close agreement between theory and experiment.

Principles of the Differential Polarized Rectifier

It is possible to interconnect two polarized rectifiers of the type shown in Figs. 1 and 12 in such a manner that if each is fed by a signal and a corresponding auxiliary signal (polarizing voltage), the detecting device (d-c galvanometer) will

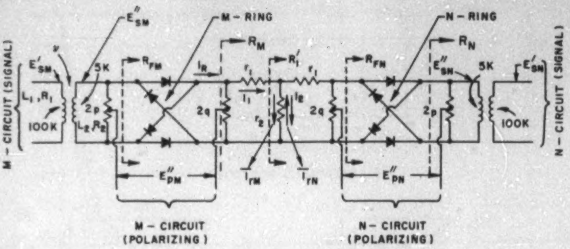

Fig. 13. Differential polarized rectifier

indicate zero current under conditions to be described.

Considering the schematic diagram shown in Fig. 13, signals E_{sM}' and E_{sN}' coming from two signal channels *M* and *N*, act upon the primaries of two signal transformers, establishing E_{sM}'' and E_{sN}'' respectively, across the secondaries of these transformers. Auxiliary voltages E_{pM}'' and E_{pN}'', supplied by polarizing channels *M* and *N*, are established at the (adjustable) mid-points of the respective resistors $2p$ and $2q$. (All voltage values refer to the magnitudes of the voltage phasors.)

Assuming for simplicity that the signals E_s contain only the fundamental frequency, equation 25, as far as the *m*-side is concerned, may be interpreted to mean that a direct current $I_{rM}=K_M E_{sM}' \cos \varphi_M$ flows through resistance r_2 in the assumed direction indicated in Fig. 13. The phase angle φ_M is understood to be the one between the phasors e_{sM}'' and e_{pM}''. Assuming now that the polarity of the voltages applied to the *N*-side is the same as that of the corresponding voltages of the *M*-side and that the ring configurations are connected as indicated, it becomes obvious that $I_{rN}=K_N E_{sM}' \cos \varphi_N$ will flow through r_2 in the opposite direction. Thus $I_r=I_{rM}-I_{rN}=0$ only if

$$K_M=K_N$$

and

$$E_{sM}' \cos \varphi_M=E_{sN}' \cos \varphi_N$$

That such a differential polarized rectifier may be employed as a basis for a true null indicator is described elsewhere.[3] It will now be shown numerically how the analysis developed in the Appendix can be utilized to determine the minimum value E_s' (say E_{sM}') required under special conditions.

Suppose the peak voltage across one of the elements is 0.1 volt. Then the peak forward current, according to Fig. 7(A) is only 0.032 milliampere and the minimum dynamic resistance is 1,050 ohms. The forward-and-backward dynamic resistances, plotted against the relative quarter-period time scales, are shown as curves 2 in Fig. 8. For the forward quarter-cycle the time-average dynamic resistance becomes 2,900 ohms and thus the effective dynamic resistance computes to 1,745 ohms. The effective dynamic resistance for the backward quarter-cycle is, as previously, 10,800 ohms. Hence, by equation 17, $S=4{,}350$ ohms. Referring to Fig. 13 it becomes clear that equation 23 may be used if r is replaced by (r_1+R_1') and if the result is multiplied by (R_1'/r_2).

The numerical values assumed in connection with Fig. 13 are those arising from the circuit described elsewhere[3] and are kept here.

Considering the *N*-ring terminated in $2p=5{,}000$ ohms and a 5,000-ohm transformer impedance in parallel, i.e., in $R_N=2{,}500$ ohms equation 19 yields $R_{FN}=3{,}940$ ohms. Thus, with $2q=5{,}500$ ohms, $r_1=5{,}000$ ohms and $r_2=20{,}500$ ohms, $R_1'=5{,}380$ ohms is obtained. Hence, equation 23 should be multiplied by $(5{,}380/20{,}500)=0.2625$, and $r=10{,}380$ should be used. Thereupon $g_G=0.994\times 10^{-6}$ mho. For the calculation of ρ_0 from equation 16, the *M*-ring is seen to be terminated in $R_M=3{,}590$ ohms, so that $R_{FM}=4{,}200$ ohms and $R_0=2{,}280$ ohms. If the frequency is taken as 10 cycles per second and the experimentally obtained transformer constants are $L_1=19{,}510$ henrys, $R_1=31{,}000$ ohms, $R_2=2{,}150$ ohms, and $\nu=4$, there results $\rho_0=0.08975$.

Next, it will be assumed that detection of ±1/2 mm is possible. Then, to detect variations with an error of 1 per cent, the deflection should be $\delta_{\min}=50$ mm. Therefore equation 26 yields the minimum required voltage E_s' at the primary of the transformer

$$E_s'=\frac{\delta_{\min}\,\sigma_G}{\left(\frac{2}{\pi}\right)g_G\rho_0}=0.0346 \text{ volt peak}$$

if $\sigma_G=4\times 10^{-10}$ ampere per mm is further assumed.

Conclusion

It has been shown by oscillographic technique as well as by direct observation of a long-period d-c galvanometer that the analytical expression derived for the d-c response of a polarized rectifier (involving errors sufficiently small) represents a reliable result. This was demonstrated for various types of signals. However, it is necessary to follow some empirical rules in numerical work, unless an unwarranted complexity involving nonlinear mathematics is introduced. The analytically obtained transient response is also corroborated by experiment. It is therefore felt that this discussion adds materially to a better understanding of the mechanism of operation of the polarized rectifier of the ring modulator type.

Appendix. Communication, Galvanometer, and Other Physical Factors

In the polarizing rectifier, Fig. 12(A), the polarizing circuit may be omitted entirely if only its effect on the ring is preserved. In the equivalent circuits *I*, Fig. 12(B), the semiconductor lattice is replaced by a pair of relatively low resistors r_f (forward or conducting) and a pair of relatively high resistors r_b (backward or blocking), assumed to be constant during the entire 1/2-cycle and changing location (within the lattice) abruptly as the signal voltage e_{s0} changes polarity between 1/2-cycles. For either 1/2-cycle, signal current flows mainly through r_f resulting in the invariance of the direction of i_R. The polarizing voltage e_{p0} in conjunction with the ring thus acts exactly as if a double-pole double-throw switch were operated synchronously, commutating the input voltage e_{s0} but leaving the lattice intact: this is illustrated by the equivalent circuit *II*, Fig. 12(C).

This point of view leads to the mathematical formulation that it is only necessary to multiply the output current by a time function $F(t)$, the commutating function, having the shape shown in Fig. 12(D), to obtain the combined effect of the interaction of the polarizing voltage and the semiconductor ring circuit upon the signal voltage. $F(t)$ has the value +1 for one 1/2-period of duration π/ω and the value −1 for the next 1/2-period. This concept was first applied to modulator theory[4] and is here adapted to the polarized rectifier, which is merely a special case of the latter.

The Fourier series for the function $F(t)$ may be obtained without difficulty, the result being

$$F(t)=\frac{4}{\pi}\sum_{n=1}^{n\,\mathrm{odd}}\pm\frac{\cos n\omega t}{n}=\frac{4}{\pi}\left(\cos\omega t-\frac{1}{3}\cos 3\omega t+\frac{1}{5}\cos 5\omega t\ldots\right)\qquad(5)$$

Without loss of generality, the signal output current when no commutation takes place may be assumed to be

$$i_{R_{NC}}=\sum_{m=1}^{m}I_{Rm}\cos(m\omega t+\varphi_m)\qquad(6)$$

Now, to obtain the effect produced by commutation, it is necessary only to perform the operation

$$i_{RC}=i_{R_{NC}}F(t)\qquad(7)$$

for each component of the two series.

The formulation for the rectified component of i_{RC} is given in terms of an average for an infinitely long time, i.e.

$$I_{R_{DC}}=\lim_{T\to\infty}\frac{1}{T}\int_0^T i_{RC}(t)dt\qquad(8)$$

The contribution of the nth harmonic of $F(t)$ and the mth harmonic of $i_{R_{NC}}$ upon $I_{R_{DC}}$ is therefore

$$I_{R_{nm_{DC}}}=\lim_{T\to\infty}\frac{1}{T}\frac{4}{\pi}\frac{I_{Rm}}{n}\int_0^T\pm\cos n\omega t\cos\times(m\omega t+\varphi_m)dt\qquad(9)$$

The definite integral is

$$J=\int_0^T\cos n\omega t(\cos m\omega t\cos\varphi_m-\sin m\omega t\sin\varphi_m)dt=\frac{1}{2}\cos\varphi_m\times\left(\frac{\sin(m-n)\omega t}{\omega(m-n)}+\frac{\sin(m+n)\omega t}{\omega(m+n)}\right)_0^T+\frac{1}{2}\sin\varphi_m\left(\frac{\cos(m-n)\omega t}{\omega(m-n)}+\frac{\cos(m+n)\omega t}{\omega(m+n)}\right)_0^T\qquad(10)$$

Since the sin- and cos-functions have a bound at ±1, examination of equation 10 reveals that no matter how closely $m\to n$. but as long as $m\neq n$, J remains $<\infty$ and hence, in the limit, equation 9 yields $I_{R_{nm_{DC}}}=0$. To obtain the limit for $m=n$ it is best to substitute first $\epsilon=m-n$ into equation 10 and then to go over to the limit $\epsilon\to 0$

$$J=\lim_{\epsilon\to 0}\left[\frac{1}{2}\cos\varphi_m\left(\frac{\sin\epsilon\omega T}{\omega\epsilon}+\frac{\sin(\epsilon+2n)\omega T}{\omega(\epsilon+2n)}\right)+\frac{1}{2}\sin\varphi_m\left(\frac{\cos\epsilon\omega T}{\omega\epsilon}+\frac{\cos(\epsilon+2n)\omega T}{\omega(\epsilon+2n)}-\frac{1}{\omega\epsilon}-\frac{1}{\omega(\epsilon+2n)}\right)\right]$$
$$=\frac{1}{2}\cos\varphi_m T+\left(\frac{1}{2}\cos\varphi_m\frac{\sin 2n\omega T}{2n\omega}+\frac{1}{2}\sin\varphi_m\frac{(\cos 2n\omega T-1)}{2n\omega}\right)\qquad(11)$$

If this is substituted into equation 9, the limiting process $T\to\infty$ is completed and it is remembered that m merges with n, there obtains

$$I_{Rm_{DC}}=\pm\frac{2}{\pi}\frac{I_{Rm}}{m}\cos\varphi_m\qquad(12)$$

Therefore, the total contribution to the rectified current is

$$I_{R_{DC}}=\frac{2}{\pi}\sum_{m=1}^{m\,\mathrm{odd}}\frac{I_{Rm}}{m}\cos\varphi_m,\ m=1,-3,+5,-7,\ldots\qquad(13)$$

and the direct current flowing in the galvanometer branch finally becomes

$$I_{r_{DC}}=\frac{2}{\pi}\sum_{m=1}^{m\,\mathrm{odd}}\frac{I_{rm}}{m}\cos\varphi_m,\ m=1,-3,+5,-7,\ldots\qquad(14)$$

Referring now to the transformer coupling of the signal energy, Fig. 12(E), it will be assumed that the magnetic paths which the flux must take in linking the primary, the secondary, and the mutual turns are identical: this implies zero leakage flux,[8] an idealized condition assumed to exist for the frequency range under consideration and, while never met in practice, nevertheless resulting in a fair approximation; from the standpoint of analysis the simplification is, of course, enormous. Thus, letting

$$\begin{aligned}L_1&=K_1N_1^2\\L_2&=K_2N_2^2\\M&=KN_1N_2\end{aligned}\qquad(15A)$$

where K is essentially the permeances of the flux path and N the primary and secondary turns, and stipulating that

$$K_1=K_2=K\qquad(15B)$$

there results

$$L_2=L_1\frac{1}{\nu^2}\qquad(15C)$$

and

$$M=\sqrt{L_1L_2}=L_1\frac{1}{\nu}\qquad(15D)$$

where ν is the primary-to-secondary turns ratio. For such a transformer the magnitude of the output voltage E_{so} in terms of the input voltage E_s takes on the following expression, easily derivable from the coupled circuit of Fig. 12(E)

$$E_{so}=E_s\times\frac{\nu\omega L_1R_o}{([R_1(R_2+R_o)\nu^2]^2+(\omega L_1)^2[R_1+(R_2+R_o)\nu^2]^2)^{\frac{1}{2}}}=E_s\rho_o\qquad(16)$$

Here ρ_o is the magnitude of the transmission ratio and R_o = total load resistance upon which the transformer works [see Fig. 12(A].

The resistance looking into the terminated four-pole R_ν of Fig. 12(A), is available in terms of the image characteristic resistance S and the image transfer factor, ζ from general network theory.[8] Both of these are real quantities in this particular case and are expressible in terms of the lattice elements r_f and r_b. Steady-state lattice theory is convenient and justifiable because of the simplifying assumptions of constant, nonreactive lattice elements; transient state, as far as the loaded four-pole is concerned, thus does not exist as the ring elements are commutated. For the symmetrical lattice under consideration

$$S=(r_fr_b)^{\frac{1}{2}}\qquad(17)$$

$$\zeta=\ln\left(\frac{(r_b/r_f)^{\frac{1}{2}}+1}{(r_b/r_f)^{\frac{1}{2}}-1}\right);\ e^{-\zeta}=\frac{S-r_f}{S+r_f}\qquad(18)$$

In terms of these, the resistance R_ν becomes

$$R_\nu=S\frac{R+S\tanh\zeta}{S+R\tanh\zeta}=\frac{R(S^2+r_f^2)+2S^2r_f}{(S^2+r_f^2)+2Rr_f}\qquad(19)$$

The load resistance R_o in equation 16 is the parallel combination of $2p$ and R_ν. The situation is now equivalent to the one in which a generator with electromotive force $|e_{so}|$ and with zero internal impedance feeds the lattice. For this case the magnitude of the output current, I_R, in terms of S and ζ becomes

$$I_R=E_{so}\frac{2}{S+R}e^{-\zeta}\frac{1}{1-\dfrac{S-R}{S+R}e^{-2\zeta}}\qquad(20)$$

If equation 18 is substituted for $e^{-\zeta}$ and $e^{-2\zeta}$, equation 20 yields

$$I_R=E_{so}\frac{S^2-r_f^2}{R(S^2+r_f^2)+2S_{r_f}{}^2}\qquad(21)$$

Since, furthermore

$$I_r=I_R\frac{R}{r}=I_R\frac{2q}{r+2q}\qquad(22)$$

the result becomes

$$I_r=E_{so}\frac{(S^2-r_f^2)}{r(S^2+r_f^2)+S^2r_f\left(\dfrac{r+2q}{q}\right)}=E_{so}g_G\qquad(23)$$

where g_G = transfer conductance, transferring a voltage applied to the input of the lattice to the galvanometer current.

Combining equations 16 and 23 and considering the mth harmonic

$$I_{rm}=E_{sm}\rho_{om}g_G\qquad(24)$$

Substituting this into equation 14, the d-c galvanometer current is brought in the form

$$I_{r_{DC}}=\frac{2}{\pi}g_G\sum_{m=1}^{m\,\mathrm{odd}}\frac{E_{sm}\rho_{om}}{m}\cos\varphi_m,\ m=1,-3,+5,-7,\ldots\qquad(25)$$

It should be kept in mind that φ_m is understood to refer to the phase displacement existing between signal voltage e_{so} and polarizing voltage e_{po} at the secondaries of the isolation transformers, while E_{sm} refers to the signal amplitude at the primary of the signal isolation transformer.

Introducing the galvanometer sensitivity σ_G in amperes per mm, the expression for the galvanometer deflection δ in mm becomes

$$\delta=\frac{2}{\pi}\frac{1}{\sigma_G}\sum_{m=1}^{m\,\mathrm{odd}}\frac{E_{sm}\rho_{om}}{m}\cos\varphi_m,\ m=1,-3,+5,-7,\ldots\qquad(26)$$

Turning now to the transient response, it will be assumed that

$$i_{R_{NC}}(t) = I_R \epsilon^{-\alpha t} 1 \qquad (27)$$

i.e., that it represents an exponentially decaying unit function. Considering only one term of the summation of equation 25, equation 7 becomes

$$i_{R_C}(t) = \frac{4}{\pi} I_R \frac{1}{n} \epsilon^{-\alpha t} \cos n\omega t \, 1 \qquad (28)$$

Using the appropriate identity of operational calculus transforming a time function into an equivalent operator

$$\epsilon^{-\alpha t} \cos n\omega t \, 1 = \frac{p(p+\alpha)}{(p+\alpha)^2 + n^2\omega^2} 1 \qquad (29)$$

the operational response then becomes the following

$$i_{R_C}(p) = \frac{4}{\pi} I_R \frac{\dfrac{p(p+\alpha)}{n}}{(p+\alpha)^2 + n^2\omega^2} 1 \qquad (30)$$

the solution of which, by means of the expansion theorem, is

$$i_{R_C}(t) = \frac{4}{\pi} I_R \frac{1}{n} \epsilon^{-\alpha t} \cos n\omega t \qquad (31)$$

which means that the response to an exponentially decaying step function is an exponentially decaying cosine wave. However, the commutating function, equation 5, is a summation of cosine waves producing a square wave. Thus the complete transient response will be an exponentially decaying square wave.

A New Telegraph Serviceboard Using Electronic Circuits

THE large increase in the use of teletypewriters in the Bell System in recent years has necessitated the development of improved arrangements for interconnecting telegraph facilities to form the networks employed by private-line services (also called leased-wire services). Greater flexibility is required in order to permit these networks to be built up and rearranged quickly to meet ever-changing customer requirements. With continuous improvements in the operating stability and reliability of telegraph line facilities, together with greatly increased demands from government and industry, private-line networks have become vastly complex.

Bell System telegraph service now uses the teletypewriter almost entirely, and manual Morse service is pratically negligible. Many networks extend over large areas of the nation, terminating in a number of cities. One employs about 85,000 miles of line facilities and another includes approximately 1,500 teletypewriter stations. These large networks are arranged for half-duplex service, which permits only one station to send at a time to all other stations on the network, and a large proportion of the stations are arranged for receiving-only operation. Such networks commonly serve government agencies, airlines, news agencies, financial institutions, and industrial organizations. Many operate at the higher teletypewriter transmitting speeds. Any false pulse or "hit" occurring on such a circuit will often interfere with transmission on the entire network unless it occurs on a 1-way branch, in which case its effect will be less serious. A disturbance of longer duration such as a steady space signal will interrupt service until located and removed. Even short interruptions to service on the more complex networks are likely to prove costly and result in serious inconvenience to the customer. Effort is necessary to reduce such occurrences to a minimum, and much development work has been directed toward improving present telegraph administrative arrangements which are performed largely at telegraph testboards. The results of this effort have culminated in the development of a new form of testboard known as a telegraph serviceboard which employs an electronic type of hub circuit to facilitate the interconnection and rearrangement of lines and loops for private-line telegraph service. (This is a multiple rather than the conventional series form of telegraph interconnection.)

Operating experience has indicated the importance of concentrating the telegraph administrative work in the hands of a minimum number of competent service attendants. This not only assures high efficiency in the performance of the work and faster restoration of service in case of trouble, but also provides economies in telegraph operating costs.

The new serviceboard accomplishes this centralization of effort by concentrating a larger work load in one position where it is easily accessible to an attendant. It employs a switchboard type of section with small strip-mounted jacks which enable an attendant to carry on his work from a seated position. The working load now handled at a single serviceboard position would occupy three or four positions of telegraph testboard. By

utilizing the hub circuit principle and other advanced operating features, the work of the attendant is made simpler and easier and the objective of concentrating a higher work load in one position has been attained.

Service Features

GENERAL

The work at the serviceboard is mainly of two types; namely, that of establishing and rearranging private-line networks to meet customer requirements and that of testing and maintaining these networks and their component line and loop facilities. Line facilities or telegraph intercity trunks include a repeater at each terminal. They are usually capable of operating full duplex (transmitting in both directions simultaneously) but are most often employed for half-duplex service (transmitting in only one direction at a time). Loop facilities interconnect the serviceboard and the customer's station and include an electronic repeater at the serviceboard office for hub circuit operation.

Line facilities are often used interchangeably for private line or for trunks used in the teletypewriter exchange service (TWX) which is also furnished by the Bell System. In TWX service the facility interconnecting the customer's station and the TWX switching center is called a subscriber line circuit. TWX subscriber line circuits do not terminate in the telegraph serviceboard. Although the switching of TWX subscriber lines and trunk circuits is performed at TWX switchboards or by TWX automatic equipment, the assignment and interconnection of line facilities to TWX intertoll trunk circuit equipment and the maintenance of these facilities is a function of the serviceboard.

DIRECT-LEG VERSUS HUB CIRCUIT OPERATION

Two different circuit arrangements are employed for interconnecting line and loop facilities at a serviceboard. Networks which involve only two legs or branches, such as a line and a loop or two lines, are likely to require little service attention and are usually interconnected directly on a simple balanced loop or neutral basis using relay-type repeaters. This arrangement, which provides so-called "direct-leg" operation, is employed for all TWX intertoll trunk circuits in addition to 2-leg private-line networks. Networks involving three or more legs and all those requiring signal regeneration are interconnected by means of an electronic hub circuit in order to simplify network changes, to expedite testing and maintenance, and to permit the use of electronic regeneration.[1]

The direct-leg principle of interconnecting legs is essentially the same as the older conventional arrangements heretofore employed at telegraph testboards. The loop conductors are connected directly to the legs of the line repeater as shown in Fig. 1 and transmission is on a polar or neutral basis. Direct-leg connections require no electronic hub terminating equipment and as approximately 60 per cent of the networks (including TWX trunk circuits) include only two legs, the equipment savings are more than ample to justify the diversity of operating methods which are imposed by the two types of interconnection. Circuits connected on a direct-leg basis are terminated in facility positions of the serviceboard, whereas those arranged for hub circuit operation appear in service positions.

Facility and service positions of the telegraph serviceboard are shown respectively in Figs. 2 and 3. Fig. 4 shows a hub circuit network which includes two lines and a loop with optional provision for electronic regeneration. Each line facility terminates in an electronic hub adapter called a coupling unit, and the loop terminates in an equivalent adapter called a loop repeater. Fig. 5 shows these electronic units. While only three legs are shown in Fig. 4, such a hub may include a maximum of from 12 to 20 legs depending on certain factors which are discussed later. This form of operation is also half duplex, and when regeneration is provided, a single unidirectional regenerative repeater serves the hub, regenerating the signals from any leg to all other legs. This provides so-called multiway regeneration, which is more economical in the use of regenerative repeaters than older, conventional telegraph circuits.

SERVICEBOARD TERMINATING AND PATCHING ARRANGEMENTS

Telegraph line and loop facilities are normally cross-connected to form the network layout specified by the customer. When orders are received for new networks or modifications of existing layouts, the work is usually done quickly on a temporary basis by manual patching

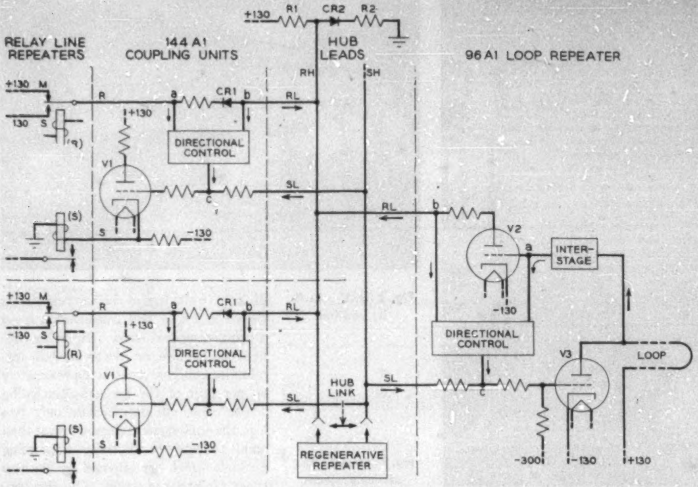

Fig. 4. Electronic hub circuit comprising two lines and a loop leg

at the board. Some time later, when the network is idle, the temporary arrangements are replaced by more permanent cross-connections between facilities or legs. Patches are also employed to introduce spare facilities quickly for the purpose of replacing assigned facilities on which trouble has developed. No effort is made to clear these troubles until the assigned facility that is in trouble has been released from service. The face of the board is ordinarily free from patching cords except when required for temporary rearrangements or for testing.

The ease with which these temporary patches may be used to expedite building up new networks and to modify existing layouts is one of the important features of the serviceboard. It is made feasible by the use of the electronic hub circuit because network changes do not affect the hub circuit currents and because all facilities (line or loop) terminate in a uniform manner. Another important advantage of the hub circuit is that transmission through it is practically independent of the number of legs connected to the hub within wide limits. A hub can accommodate from 12 to 20 legs, the exact number depending on the ratio of electronic coupling units to loop repeaters used, the capacity of the hub leads to ground, and whether or not regeneration is provided.

For hub circuit operation, each line or loop facility terminates in a legs relay circuit which is associated with a legs jack appearance in the face of the service position (see Fig. 6). An electronic regenerative repeater is terminated in a similar manner except that it is associated with a hub relay and legs jack circuit. The legs jack circuits of all line and regenerative repeater facilities have jack appearances in all service positions; only spare loops have these multiple jack appearances. All multiple legs jack appearances are equipped with idle indicator lamps to indicate whether the facility is busy or idle. The legs jacks permit the associated facility, when spare, to be patched for service or for testing and maintenance.

When a facility is assigned for service, its send and receive legs are cross-connected to the *SH* and *RH* leads of a hub circuit and its relay circuit is cross-connected to a jack associated with the hub circuit. Line or loop legs are associated with T jacks and the regenerative repeater with the hub jack. A hit indicator lamp is located above each T jack of the hub circuit to assist in the location of troubles. A flashing lamp indicates that the leg is sending to the hub and all other lamps of the hub should remain out. Momentary or steady lighting of lamps associated with legs which are receiving from the hub is an indication of trouble.

Leg-patching cords are employed for most of the patching done in conjunction with hub circuits. The cords are located in the face of the board where they are readily accessible, and 40 cords are provided in each service position. Service patches perform three principal functions; namely, the addition of spare facilities, the substitution of spare for assigned facilities, and the building up of new networks on a temporary basis. An addition of a line or loop leg is made by patching the legs jack of the spare facility to the hub jack.

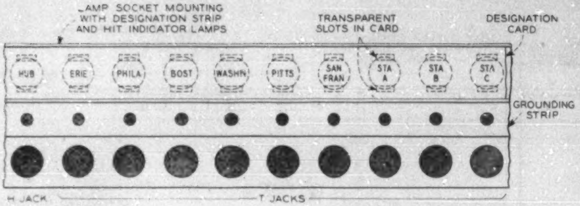

Fig. 7. Appearance of hub circuit comprising six lines and three loops in the face of service position

peater may be substituted for the equivalent assigned facility by patching its legs jack to the T or hub jack of the assigned facility. The assigned facility is automatically released from the hub with the patch. The switching is accomplished by means of the leg or hub relay, operation of which is controlled marginally from potential or ground supplied by the sleeve of the patching cord.

A hub circuit may be built up temporarily on a patch basis. This is accomplished by interconnecting patching cords which have been connected to the proper line and loop legs and to a regenerative repeater or hub link. The interconnection is accomplished by means of the hub jack in each cord circuit which provides access to the two transmission conductors.

A facility may be released from the hub by connection of a release plug (*RLS*), Fig. 6, to the corresponding T jack. This plug includes an auxiliary pin which engages with a hole in a grounding strip built into the jack mounting, Fig. 7. This serves to operate the legs relay which disconnects the *RL* and *SL* legs of the facility from the hub.

Other Improved Features

In addition to the hit indicator lamps associated with the T jacks of the concentration jack circuit, provision is made for observing hits which are reported to occur infrequently, by means of trouble indicator cords providing locked-in hit indication. With trouble indicator cords it is unnecessary for an attendant to watch continuously the hit indicator lamps associated with the concentration jack circuit when a customer reports his network to be subject to an intermittent form of trouble. For such observations the attendant connects a trouble indicator cord circuit to each leg of the network; and each position is equipped with six trouble indicator cord circuits, for this purpose. This permits the attendant to determine on which leg of the network trouble is occurring.

The serviceboard includes jack appearances of teletypewriter test signals with special means for patching them to any hub or facility where they may be required. A test signal cord circuit provides for the connection of test signals to lines or loops for long-time testing to a distant point. This cord circuit includes a feature which permits the distant attendant to stop the signals at their source and simultaneously call the local attendant for consulation.

Each position may be equipped with a telegraph signal-distorting set which permits the attendant to introduce varying amounts of distortion of any desired type on signals obtained from a test signal supply source. These distorted signals are employed to determine the transmission distortion tolerance of a circuit.

A telephone cord and set are available for communication over a telephone subscriber line and over intraoffice telephone trunks. A telegraph cord circuit provides for manual Morse monitoring and communication with hub circuits or over interoffice telegraph trunk circuits. This cord is equipped with a Morse key and sounder.

A teletypewriter cord, which is associated with the position teletypewriter, provides for monitoring and communication over interoffice trunk circuits, line or loop facilities, and hub circuits. This circuit is arranged for connection to the transmission measuring set by key operation when it is desired to measure the distortion of signals under observation by the cord circuit.

Two connecting cords are available for interconnecting interoffice telegraph trunks for through interoffice calls. These cords provide for either manual Morse or teletypewriter communication under key control. Each cord includes a disconnect feature responsive to ringing signals, which permits either the calling or called attendant to disconnect the cord from both trunk circuits electrically without attention from the local attendant. The local attendant takes down the cord later at his convenience. This feature reduces trunk-holding time on the interoffice trunks, all of which are provided with multiple jack appearances in each serviceboard.

Techniques Employed

Prior to the development of the new serviceboard, all telegraph repeaters employed polar relays. It was therefore necessary to design coupling units to connect these relay-type repeaters to the new hub arrangement. Most important of these is the *144A1* coupling unit which makes connection to the relays in a line repeater (see Fig. 5). An all-electronic loop repeater, the *96A1*, was also designed, Fig. 5. The operation of these two units is described with reference to the 3-branch hub circuit indicated in Fig. 4. Two line branches are shown connecting to the hub through coupling units and a local subscriber loop is shown connecting through a *96A1* loop repeater.

Normally only one branch of the network at a time passes signals inward to the receive hub, *RH*. During periods of no signals, all branches remain in the marking condition and are effectively disconnected from the receive hub. This is accomplished in the *144A1* unit by reverse-biased diode *CR1* and in the *96A1* repeater by tube *V2* being cut off. During this marking condition, the receive hub rests at a potential of +60 volts supplied from a terminating voltage divider (hub potentiometer) consisting of *R1*, *R2*, and *CR2*.

When an inward spacing signal is imposed by one of the line repeaters, −130 volts is applied to the *R* leg of the *144A1* unit and current is drawn from the receive hub through diode *CR1*. This drops the hub potential to the spacing value of −30 volts. Opening the loop of the *96A1* repeater causes tube *V2* to conduct current from the receive hub and likewise lower the receive hub potential to −30 volts. Thus, any branch of the network can cause a similar spacing voltage swing which is essentially independent of the number of branches being multipled at the hub. During the −30-volt space condition diode *CR2* in the hub potentiometer is reverse-biased, and effectively opens the path to ground through *R2*. This minimizes the drop in hub resistance during the space condition and enables the −30-volt potential to be reached with less current flow in the transmitting leg. The more constant hub resistance also results in a nearly symmetrical hub signal wave and minimizes signal bias when the wave becomes rounded by capacitance to ground in a large hub circuit or concentration group.

If no regeneration is required, the receive and send hubs are directly interconnected by means of a hub link. When the two hubs are interconnected through a regenerative repeater, the same marking and spacing potentials are produced at the send hub. However, as a result of the regeneration, the signal train is delayed by one-half signal element.

The outward paths are coupled to the send hub through high resistance and are essentially voltage-operated. Consequently the voltage swing of the hub does not change materially as the number of outward paths is increased. In the *144A1* coupling unit, tube *V1* in the outward path serves to drive the send relay *S* of the line repeater in accordance with the signal on the send hub. In the *96A1* repeater, tube *V3* in the outward path repeats the signal by opening and closing the loop circuit.

ol. 74
. 1
955

The resistance of the hub circuit is about 2,000 ohms, low enough to avoid excessive crosstalk into other hubs. This permits the use of up to 10,000 feet of switchboard wire in setting up a hub connection without excessive rounding of the signal wave. The number of branches multipled at a single hub is, however, limited to about 20 because the connections are not infinite in resistance. Where a larger concentration group is required, more than one hub may be set up with interhub repeaters interconnecting them.

The *144A1* coupling unit includes a directional control feature which prevents the flow of signals outward from the send hub to the line repeater which originated them. This control includes a bistable circuit triggered by the combination of voltages at points *a* and *b*. When a space is sent through the *144A1* to the receive hub, both points swing negatively. If, however, a space is sent to the hub from some other branch, only point *b* swings negatively. This difference causes the bistable circuit to be set to indicate the direction of the last pacing pulse on the receive hub. When an inward flow is indicated, point *c* is clamped in a marking condition and outward flow of signals is blocked.

If two subscribers send simultaneously, or if one purposely breaks the sending of another, two space signals may be impressed on the receive hub. This is known as a double space and results in a hub potential of −60 volts. The directional control is arranged so that this condition will unblock the outward paths of those branches sending the spaces to the hub so that all branches receive a space condition. This has been called a double-space by-pass and insures that all spaces sent inward from one branch are transmitted outward on the other branches and are never lost because of a prior space condition on the hub. This makes simultaneous sending immediately evidenced by garbled local copy, and gives a quicker "break."

As mentioned, the *96A1* loop repeater transmits to the loop on an open-and-close basis. This is made practical by the high dynamic plate resistance of tube *V3*, which sends a symmetrical current wave into the loop even when it consists of 25 miles of cable pair. This results in unbiased signals at the subscriber's equipment without need of any adjustments.

Transmission from the subscriber is also on an open-and-close basis but the signal is received at the *96A1* on a voltage basis. In the normal marking condition of the loop, the potential at the plate of *V3* is −50 volts. When the loop is opened at at the subscriber's unit, the plate falls to nearly −130 volts. This voltage swing is inverted and coupled to tube *V2*, which in turn transmits to the receive hub. When a space is sent toward the subscriber, the plate potential of *V3* swings postitive and thus a mark condition is held toward the hub. The high dynamic plate resistance of *V3* causes the voltage wave received from the subscriber to be symmetrical, and no signal bias occurs as the length of loop is increased. Furtherfore, no inductive loading at the subscriber's unit is necessary as when receiving on a current basis.

The *96A1* repeater also has a directional control feature similar to that in the coupling unit. This serves to hold *V3* conducting when sending toward the hub. This directional feature does not need to recognize a double space since

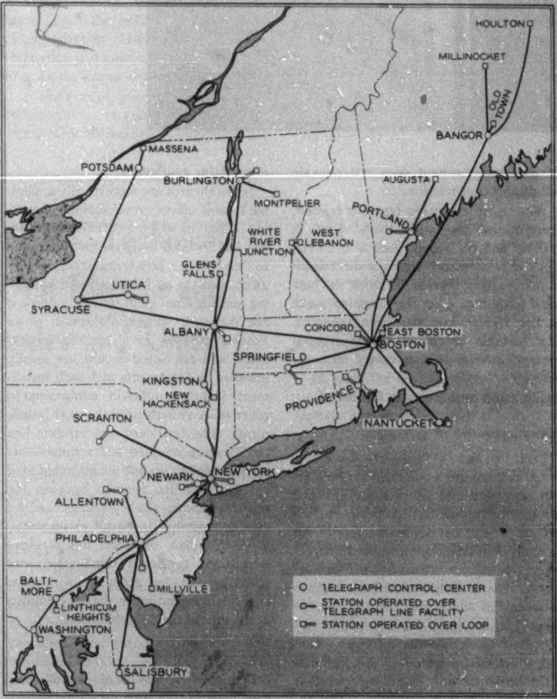

Fig. 8. A complex half-duplex private-line network

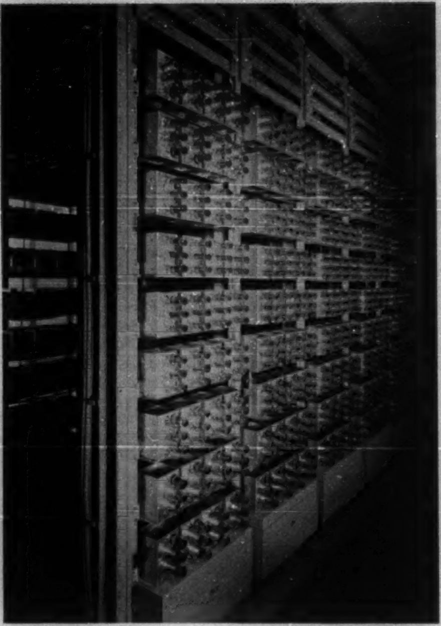

Fig. 9. Bay-mounting arrangements for electronic loop repeaters

the subscriber's loop does not provide full-duplex transmission.

When a regenerative repeater is used, there are intervals when the send hub is spacing and the receive hub is marking. Thus it is necessary that the directional control feature be able to block the outward path even after the incoming space to the receive hub has been removed. The bistable circuit in the directional control provides this necessary memory.

Application and Results Achieved

APPLICATION

Each line or loop facility requires electronic terminating equipment for hub circuit operation and hence a serviceboard installation involving 100-per-cent hub circuits would cost somewhat more than an equivalent telegraph testboard. In replacing existing testboards with serviceboards it is desirable to strike a balance between this added cost and the benefits derived from operating economies and improved service to the customer. One step which has been made in this direction is the introduction of direct-leg operation for simple, 2-branch networks. This results in material savings in electronic terminating equipment.

Serviceboards are more readily applicable to new offices, or relocations of existing offices, in which case new line facilities are installed designed for connection to electronic hub-terminating equipment, and the added expense of modifying existing equipment for this purpose is not incurred. When conversion of an existing office is involved, the serviceboard and associated circuits are usually installed in increments and each installment includes sufficient equipment to cover office growth until the next installment. The testboard and existing line facilities are retained and arrangements are provided to permit the interchange of old and new line facilities between the testboard and serviceboard so as to afford greater flexibility in circuit assignments. With this plan, the older line facilities with their testboard terminations are scheduled to be replaced with new facilities terminating in the serviceboard at the time of their obsolescence.

RESULTS ACHIEVED

Complete serviceboard installations have been in operation for about 2 years in new offices at Oakland, Calif., Portland, Ore., Chicago (Stewart), and New York (West 50th Street). Operating experiences in these offices have been most gratifying. Troubles can be directionalized, sectionalized, and removed more quickly than with testboards.

An improved feature of importance which has not been mentioned previously is the hub circuit jack field arrangement. This is so simple that an attendant can determine at a glance the layout of a complicated network. The simplicity of a concentration jack circuit appearance in the service position is evident from Fig. 7. With testboard operation the attendant must read the designation cards over many jacks and in some cases refer to layout sketches to obtain this information. Another factor contributing to the difficulty in determining the nature of a circuit layout in a testboard office is the relative nonuniform manner in which networks are interconnected in these offices. The same group of facilities may be interconnected in a number of ways in a testboard, whereas there is little, if any, variation permissible in a hub circuit network.

These improvements provide better service and permit more circuits to be handled per attendant. However, the maximum operating efficiency obtainable with serviceboard arrangements cannot be realized until serviceboards have been installed in all of the larger offices. This is because interoffice teamwork is involved in performing certain operations and if one office is appreciably slower than another, the higher efficiency of the faster office is not fully effective.

The training problem has been simplified because the uniform termination of facilities in serviceboard offices has permitted the adoption of standard procedures for testing and patching. In the case of testboard operation, layouts are so varied that it is difficult to establish standard procedures for testing and patching operations to cover all network arrangements, and each attendant must develop his own technique from knowledge based on previous experience with similar networks.

The West 50th Street office in New York is considered a typical serviceboard office. It includes five service positions which are shown in Fig. 3 and two facility positions which are currently used to interconnect 600 line facilities, 520 2-way loop facilities, and 113 1-way loop facilities to form 241 TWX trunk terminals, 23 TWX through circuits, 184 private-line terminal circuits, and 42 private-line networks arranged for hub circuit operation. Each TWX or private-line terminal circuit requires the interconnection of a line facility and either a trunk terminal or a loop. The number of line and loop facilities required for the private-line hub circuit networks will vary from 3 to usually not more than 20 facilities depending upon the circuit complexity. The average for the 42 circuits at West 50th Street is 2.1 line facilities and 2.4 loop facilities. A typical complex half-duplex network terminating in a hub circuit at West 50th Street, New York, is shown in Fig. 8. This layout includes six legs at New York and nine at Boston.

HEAT PROBLEM

A new problem which has been encountered in connection with the development of the telegraph service board is that of removing heat dissipated by the small, compactly mounted electronic equipment. The manner in which these demountable units are bay-mounted is shown in of Fig. 9, which shows several bays of loop repeaters. Owing to the relatively small amount of heat dissipated by the older relay-type telegraph repeaters and the relatively large areas which they occupy in the bay, heating heretofore has been no problem in telegraph offices. The heating problem has two important aspects, namely, the protection of the electronic apparatus components from excessive temperature rise and the prevention of excessive operating room temperatures.

Several steps have been taken to minimize excessive heating. It has been determined by field experience that the maximum allowable heat dissipation per bay should be limited to 1,000 watts. When several adjacent bays are occupied by hot equipment, it is desirable either to provide greater separation between these bays or to maintain the total dissipation per bay well below 1,000 watts. This is necessary in order to protect apparatus units such as resistors, varistors, and condensers.

Certain design features have been embodied in the electronic units in order to minimize the heating problem. The units, which are all of a demountable type, are designed so that the vacuum tubes are located on the outside where heat dissipation is assisted by room air convection currents and where dissipation by the tubes is less likely to affect other apparatus located inside the unit. The unit enclosures are left open at the top and bottom and the units are arranged for closely adjacent vertical mounting so as to provide a chimney effect for the creation of a cooling air draft.

In some cases, where there are heavy concentrations of this electronic equipment, air-conditioning equipment has been installed to supplement the ventilation system normally available in the building. The air-conditioning units are commonly located along one wall of the room and the cool air is distributed throughout the room by means of ducts. The present need for such air-conditioning indicates the need for further development to reduce the heat generated in electronic units of this type.

Conclusions

The new serviceboard arrangements are an important step forward in the development of means for providing good service and for meeting the present complex requirements for teletypewriter private-line and TWX services. They also include facilities suitable for meeting future needs, considering the present trend toward higher transmitting speeds and increased complexity of teletypewriter and similar services such as teletypesetter, transmission of punched-card data, etc.

Recommendations of IEC Technical Committee No. 24 on Electric and Magnetic Magnitudes and Units

J. J. SMITH
MEMBER AIEE

A MEETING of Technical Committee (TC) 24 on Electric and Magnetic Magnitudes and Units (EMMU) was held at Philadelphia, Pa., on September 10 and 11, 1954, during the Golden Jubilee of the International Electrotechnical Commission (IEC). It should be understood that the recommendations made by this committee, and given in the following, have been referred to the national committees of the various countries for an official vote under the 6 months' rule. Thus they are not as yet official decisions. However, since each recommendation was approved by a large majority of the delegates present from the various countries, it seems reasonable to expect that they will be approved by the national committees.

It is hoped that the reader will bear in mind that each action in the following account is the best that can be agreed upon at present and should be considered as the most practical clarifying step that can be taken now. Further progress depends on: 1. a more nearly perfect understanding of the phenomenon involved, and 2. a better agreement on the meaning of the technical words or language used in the exchange of different viewpoints. Both of these will come with time. The recommendations are listed in the following.

Sign of Reactive Power

In 1935, the IEC adopted the convention that the reactive power flow to an inductive receiver be negative. In 1946, an AIEE committee undertook a survey of the prevailing practice in the United States. They found that it varied, but that most power companies assumed the sign of reactive power to an inductive receiver to be positive. In accordance with this, the AIEE changed the standard to accord with this practice. This was brought to the attention of the IEC at

Paper 55-49, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing December 8, 1954.

J. J. SMITH is with the General Electric Company, Schenectady, N. Y.

the Paris meeting in 1950 and it was suggested that other countries review their usage. Since then, many of the countries have found that they are also using the sign of reactive power to an inductive receiver as positive. It is hoped that the question will be clarified by the following resolution, which was adopted, and with which the latest American Standard is in accord. Resolved that:

1. Reactive power flow to an inductive receiver be positive.
2. Only one kind of reactive power be considered and defined. This means that no qualifying adjective should be used with the term "reactive power."
3. Reactive power be completely specified by stating its amount and direction of flow.

Name for MKS or Giorgi System

It was recommended that the system which uses the fundamental units meter, kilogram, and second (MKS) be officially known in the IEC as the Giorgi system.

It was recognized that the system which uses the fundamental units, meter, kilogram, second, and ampere is referred to by many as the MKSA system. This term is similar to the term centimeter-gram-second (CGS) system.

Assignment of Names "Magnetic Polarization," "Intrinsic Induction," and "Magnetization"

The magnetic induction B at a given point in a magnetic field is represented by a vector the magnitude of which is equal to the maximum limit of the time integral of the electromotive force generated in a small plane-conducting loop brought in from a region of zero magnetic field divided by the area, as the area approaches zero in a macroscopic sense. The maximum limit occurs for a particular orientation of the loop at the given point. The direction of the vector is normal to this loop.[1]

The magnetic field strength H at a given point is represented by the current per turn multiplied by the number of turns in a small elongated uniformly wound solenoid divided by its length when the solenoid is centered at the given point and is oriented and adjusted so as to counterbalance magnetic effects at that point.[2]

In vacuum the ratio $B/H=\mu_0$ is called the permeability of free space. In any other medium the ratio $B/H=\mu$ is called the permeability of the medium.

It was recommended that in a medium other than vacuum the term $B-\mu_0H$ be called "magnetic polarization" or "intrinsic induction," and that $(B/\mu_0)-H$ be called "magnetization." These terms are used by many authors and a name is needed for them. There was considerable discussion as to which of these two terms should be given preference in the recommendations. The views of the national committees will be obtained on this. Note: In the United States the symbol μ_v is used instead of μ_0.

Name for Unit of Magnetic Induction in Giorgi System

It was recommended that the name "tesla" be given given to the unit of magnetic induction (the weber per square meter) in the Giorgi system.

Similarly, in the centimeter-gram-second electromagnetic (CGSM) system, there is the gauss, the unit of magnetic induction, which is equal to the maxwell per square centimeter.

Rationalization of the Electromagnetic Field Equations

At the IEC 1950 Paris meeting TC 24 recommended that the MKS system be used in the rationalized form. At that time, questions were raised as to whether rationalization by change of quantities, or change of units was meant. Since then much discussion has been devoted to the subject. The following was recommended at the 1954 meeting:

"The rationalization of the equations of the Electromagnetic Field recommended by the I.E.C. is characterized by the following principal equations whose form remains the same whether the symbols are regarded as representing physical quantities coming into play or are regarded as representing their numerical values.

$$\oint H\,ds=\Sigma I$$
$$\phi=\int\int B\,dA$$
$$B=\mu H$$
$$\int\int D\,dA=Q$$
$$\psi=\int\int D\,dA$$
$$D=\epsilon E$$

"These equations apply to isotropic media. The total current (ΣI) includes in the general case the displacement current.

"The permeability of free space μ_0 has the numerical value $4\pi\times10^{-7}$, where the unit is the henry per meter. The permittivity of free space ϵ_0 has the value of $(1/c^2\mu_0)$ or approximately the numerical value 8.85×10^{-12}, where the unit is the farad per meter." (The table of references for the quantities used in the foregoing equations is shown below.)

Relation of Ampere Turn per Meter to Oersted

It was found that in the usage of various writers the relation between the ampere turn per meter and the oersted was apparently not always the same. To secure uniformity, the following resolution was adopted:

> A current of ten amperes in a wire of one centimeter length of arc, of a circle of one centimeter radius, contributes at the center of the circle a magnetic field strength of one oersted.
>
> A uniform elongated solenoid having one turn per meter axial length in which there is a current of one ampere produces at the center of the solenoid a magnetic field strength of one ampere-turn per meter.
>
> The contribution to the magnetic field strength in the first case is equal to $1{,}000/4\pi$ times the magnetic field strength in the second case.

Here the first paragraph of the resolution uses the arrangement by which the abampere was defined by means of the oersted in the British Association Reports on Electrical Standards.[3] The second paragraph uses the arrangement by which the ampere-turn per meter is defined in the IEC vocabulary.[2] The third paragraph gives the relation between the two magnetic field strengths.

It will be noted that actual numerical examples are used in the resolution. This was done to avoid the use of symbols, since these are also used in different senses by different authors. It is hoped that the resolution will produce uniformity in the relation between the ampere-turn per meter and the oersted as used in future.

Table of Reference for the Quantities in the Above Equations

Name	Symbol	Unit of the Giorgi System	IEC Classification Number
Element of Length	ds	Meter	05-35-050

Magnetic Flux	ϕ	Weber	05-25-035
Permeability	μ	Henry per meter	05-25-045

Revision of Definitions in Second Edition of International Electrotechnical Vocabulary Within Scope of TC 24

Because of certain points which were discussed in the previous resolutions in connection with definitions prepared by TC 1, TC 24 agreed that it should consider carefully the definitions which were closely allied with its activities. Some definitions to which attention had already been called were those of reactive power, complex power, permeability, and permittivity.

Comparison of Systems with Three and Four Dimensions

At the 1950 Paris meeting the IEC adopted the ampere as the fourth preferred fundamental unit in the Giorgi system. The International Union of Pure and Applied Physics (IUPAP) adopted the ampere as the fourth fundamental unit in the Giorgi system in 1951.

Thus the MKSA system is based on four fundamental units (meter, kilogram, second, and ampere). The two CGS systems (electrostatic and electromagnetic) are based on three fundamental units (centimeter, gram, and second). In the CGS electromagnetic system, the permeability of free space is assumed to have no dimensions and its numerical value is considered equal to 1. In the CGS electrostatic system, the permittivity of free space is assumed to have no dimensions and its numerical value is taken to be equal to 1. It was agreed that the relations between these three systems, each of which is based on a different assumption, should be studied and clarified. A memorandum by Dr. H. Konig and Dr. U. Stille has been prepared on this subject and will be circulated to the national committees for study.

Preparation of Document Containing all Decisions of TC 24 Since Founding of IEC

It was agreed that such a document should be prepared by the secretariat so that all the decisions of TC 24 from its beginning to date would be readily available.

It was pointed out that reference to other sources will probably be necessary later,[1,4,5] and that as a first step collecting the IEC decisions was desirable. The work on electric and magnetic magnitudes and units is carried on in this country by the American Standards Association Committee C61.

Eddy-Current Mutual-Inductance Transducers With High-Conductivity Reference Plates

HORACE M. JOSEPH
MEMBER AIEE

NATHAN NEWMAN
NONMEMBER AIEE

Synopsis: The design considerations of mutual-inductance devices for use in noncontacting measurements of distance are studied with special emphasis on the eddy-current type utilizing "perfectly" conducting metal reference plates of infinite extent. The force on the plate due to the exciting current, typical schematic circuits used to detect the results, and the effects of rapid motion of the gauge are given. Since actual reference plates are not perfectly conducting nor infinitely extensive, some indications of the effects of finite conductivity and limited extent of reference plates are included.

THIS paper analyzes the general performance characteristics of mutual-inductance transducers. This analysis is an outgrowth of the use of the radio-frequency mutual-inductance transducer invented by M. L. Greenough. Several development projects have utilized the micrometer for specific purposes, but each design analysis was restricted to the specific application. Accordingly it was believed desirable to establish general design criteria for these mutual-inductance transducers.

Noncontacting Distance Gauges

The principal methods in use for measuring small distances by noncontacting means may be classified as optical, acoustical, and electrical. Optical methods are in wide use, but an optical path is not always available for measuring purposes. In addition, if the indication by an optical method is to be used for control purposes, the amount of energy available is so low as to require considerable amplification. Acoustical methods which are typified by sonar, also suffer from the inability to provide high-energy signals directly.

Gauges using electrical phenomena may be classified into propagation-echo types exemplified by radar (which are not suitable for use in measuring small distances) and other electrical methods that use a variation of one or more of the basic electrical parameters (resistance, capacitance, or inductance) as a function of the distance or displacement to be measured. Change in electrical resistance with displacement is not readily adaptable to noncontacting methods. Variation in capacitance is limited to the measurement of very small distances. Also it is necessary that the dielectric constant of the material between the objects whose capacitance is to be measured remain fixed. The

This paper reports the results of an investigation conducted by the Electronic Instrumentation Section of the National Bureau of Standards under a program of Basic Instrumentation Research and Development sponsored by the Office of Naval Research, the Air Research and Development Command, and the Atomic Energy Commission.

The valuable suggestions of Dr. L. S. G. Kovasznay of The Johns Hopkins University are gratefully acknowledged.

Table I. Terminology

Method of Varying Self- or Mutual Inductance	Designation of Method
Variation of effective permeability by relative motion of ferromagnetic metal in vicinity of coil(s)	Variable-mu inductance
Relative motion nonmagnetic metal plate in vicinity of coil(s) (typified by Fig. 1)	Eddy-current inductance
(a) Perfect-conductor case	(a) Perfect conductor
(b) Resistive-conductor case	(b) Resistive conductor
Relative motion of coils (or two parts of one coil) (typified by Fig. 2)	Movable-coil inductance

Table II. Comparison of Movable-Coil- and Eddy-Current-Inductance Distance-Measuring Devices

Consideration	Movable-Coil Inductance; See Fig. 2	Eddy-Current Inductance; See Fig. 1
Sensitivity at a given separation	Less than eddy current	More than movable coil
Coil support	Separate support for each coil	Common coil support
Leads	Flexible leads for movable coil Fixed leads to stationary coil	Fixed leads to both coils
Changes in mechanical alignment:		
(a) Lateral	Sensitive to lateral shift	Insensitive to lateral shift
(b) Tilt	Less sensitive than eddy current	More sensitive than movable coil
Fixed component of response	None	Must be balanced out

output of such instruments occurs at a low-energy level, and, except for very small separations, the variation is a small percentage of a fixed capacitance consisting largely of that of the leads. In a capacitance distance-measuring gauge, it is necessary either to make a connection to the reference plate or to see that the reference place is well insulated. Nevertheless this type of distance gauge has been used extensively.

Inductance-Type Distance Gauges

The remaining electrical parameter that may be varied by displacement is inductance, either self or mutual. This variation may be accomplished in a variety of ways. Table I gives the terminology used. In Table I the eddy-current inductance method is subdivided into two cases: the perfect conductor and the resistive conductor. The distinction depends upon the depth of eddy-current penetration below the surface of the plate. If this depth is negligible in comparison with all dimensions of the system, the plate will be considered as a perfect conductor. What is considered a negligible depth of penetration will be discussed later.

The following observations about the resistive conductor may be made. The effect of a resistive plate in changing a mutual inductance is less than that of a perfectly conducting plate. The greater the resistivity of the plate material, the less is the effect on mutual inductance. Furthermore, if the current at the back surface of the plate is not negligible (a thin resistive plate), the effect on mutual inductance is less than it would be with a thick resistive plate.

Self-inductance and mutual inductance are manifestations of the same phenomenon of flux linkages. For purposes of calculation, self-inductance can be considered as the mutual inductance between two identical coils in the same position. In a practical circuit, the voltage across a self-inductance must include a resistive voltage drop due to the dissipation of the winding. Since this is not necessary when using an open-circuit secondary coil coupled by mutual inductance, this type of circuit is generally more practical.

The three ways of varying inductance, listed in Table I, are quite similar and have many advantages and disadvantages in common. Some disadvantages are:

1. The circuits may be subject to resonant effects that, without careful design, may lead to instability.
2. The range of distances which may be measured is limited to those comparable to the coil diameter(s).
3. Measurements may be adversely affected by the presence of extraneous metal in the vicinity.

The advantages common to all of these inductance-type distance gauges include:

1. High-energy level output.
2. Small mechanical forces on the reference plate.
3. Stability of response.
4. Applicability to a wide range of displacements (down to as small as 1 microinch).
5. Independence of dielectric constants of materials in the gap between the fixed coil and the reference object.

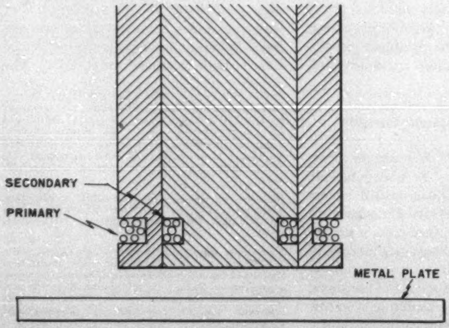

Fig. 1. Mutual-inductance probe with both coils relatively fixed on same form

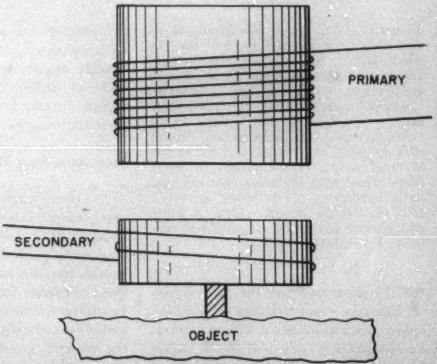

Fig. 2. Mutual-inductance probe with secondary attached to object and movable

6. Output little affected by normal lead capacitances or inductances.

The variable-mu-inductance devices, for measuring distances, are different from the eddy-current and movable-coil types in that large variations in effective permeability are easily obtained; hence the principle involved can be used to make instruments that are very sensitive to small static displacements. These devices can be used at ordinary power frequencies. Actually, they require use of a relatively low frequency which makes them unsuitable for measuring very rapid displacements. The higher magnetic fields necessary for a given voltage output cause comparatively large forces to be exerted on the reference plate. In addition variable hysteresis tends to cause some errors.

The eddy-current and movable-coil distance-measuring devices are very closely related. The same type of calculations may be used to determine the changes of mutual inductance. In a movable-coil device the output is the direct (inverse) function of separation distance. In the eddy-current device the output is the difference between a fixed quantity and an inverse function of separation distance. Accordingly, for large distances compared to the radius of the coil, the movable coil is preferable. These features are compared in Table II.

This paper relates primarily to eddy-current-inductance distance-measuring gauges. Inasmuch as the process of obtaining the solution to the eddy-current method involves the calculation of the mutual inductance between pairs of coils, a considerable part of the information included is applicable to the movable-coil system. The variable-mu method will not be treated, nor will the effects of heating of the reference plate be considered.

Nomenclature

$j=\sqrt{-1}$
$\omega=2\pi f$ (f = frequency, cycles per second)
$I_{1\,\max}$ = maximum value of primary current, amperes
I_1 = rms value of primary current, amperes
$I_{1\,\max}'$ = maximum value of current in image of primary coil, amperes
I_1' = rms value of current in image of primary coil, amperes
$R_{2\max}$ = maximum value of open-circuit voltage across the secondary coil, volts
E_2 = rms value of open-circuit voltage across the secondary coil, volts
M_{12} = mutual inductance between primary and secondary coils, henrys
M_{12}' = mutual inductance between image of the primary coil and the secondary coil, henrys
n_1 = number of turns on the primary coil
n_2 = number of turns on the secondary coil
A = average radius of the primary coil, centimeters (as in Fig. 6)
a = average radius of the secondary coil, centimeters (as in Fig. 6)
x = distance between the planes at the centers of the two coils under consideration, centimeters
y = a function of a/A and x/A
d = distance between a plane at the center of the secondary coil and the reference plate, centimeters (as in Fig. 6)
b = distance between planes at the centers of the primary and secondary coils, centimeters (as in Fig. 6)
η = fractional deviation of a curve from a straight line tangent to the curve at some reference point
$S_m=\dfrac{dM}{dx}$ (inductance sensitivity)
μ = magnetic permeability
ϵ = dielectric constant
σ = conductivity
L = length
f = frequency $\left(f=\dfrac{\omega}{2\pi}\right)$
C_1 = constant for specific parameter values
C_2 = constant for specific parameter values

Analysis

Phenomenologically a mutual-inductance transducer of the eddy-current perfect-conductor type operates as follows. The voltage induced in the open-circuit secondary coil by the primary coil current is diminished by bringing a metal plate near the secondary coil; the closer the plate, the greater the decrease in induced voltage. This induced voltage is proportional to the effective mutual inductance between the primary and secondary coils, and can be calibrated as a function of the separation between the coil system and the reference plate.

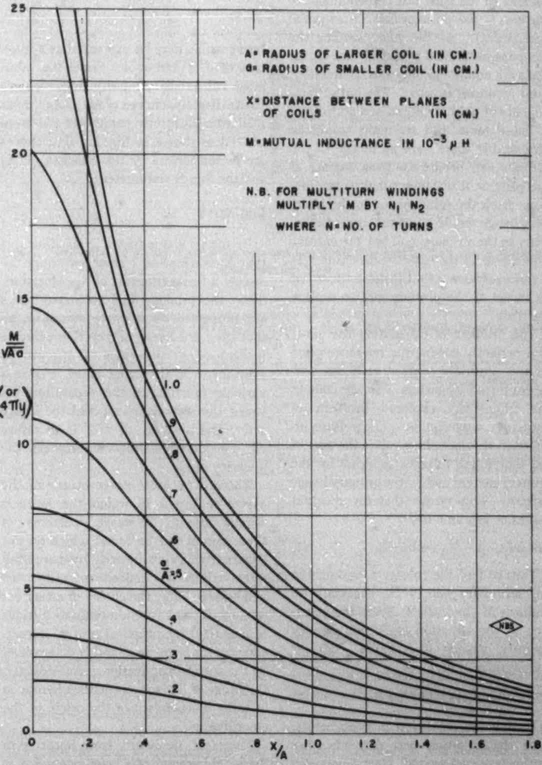

Fig. 3. Mutual inductance between two single-turn coaxial coils versus displacement between them

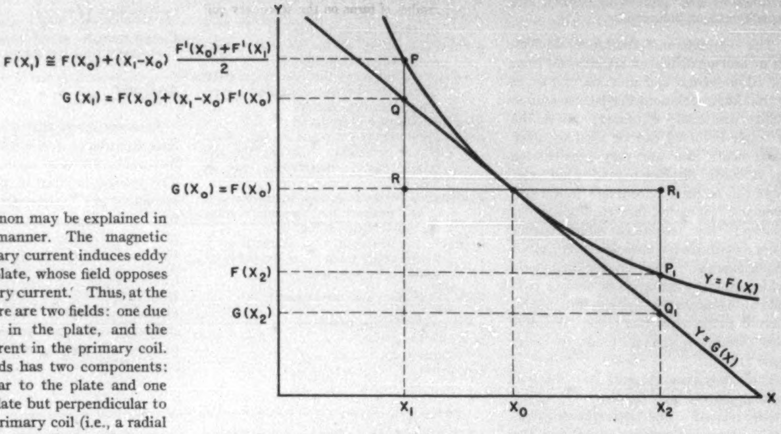
Fig. 4. Reference figure for definition of range of linearity



$F(X_1) \cong F(X_0)+(X_1-X_0)\dfrac{F'(X_0)+F'(X_1)}{2}$
$G(X_1) = F(X_0)+(X_1-X_0)F'(X_0)$
$G(X_0) = F(X_0)$
$F(X_2)$
$G(X_2)$
Y
P
Q
R
R_1
P_1
Q_1
$Y = F(X)$
$Y = G(X)$
X_1
X_0
X_2
X

This phenomenon may be explained in the following manner. The magnetic field of the primary current induces eddy currents in the plate, whose field opposes that of the primary current. Thus, at the plate surface there are two fields: one due to the currents in the plate, and the other to the current in the primary coil. Each of the fields has two components: one perpendicular to the plate and one parallel to the plate but perpendicular to the axis of the primary coil (i.e., a radial component). At the plate surface the components of field perpendicular to the plate are equal and opposite in direction; their resultant is zero. The radial components of field are equal and additive.

These same field strengths would be produced if there were an image[1] of the primary coil behind the front surface of the plate at a distance equal to the distance from the primary coil to the plate. This image would be of the same dimensions as the primary coil but the current would flow in the opposite direction. It is this equivalence that justifies the use of an image of the primary coil to replace the plate.

The problem of calculating the effect of a perfectly conducting reference plate on two mutually coupled coils can now be converted by means of image coils to the extensively explored problem of mutually coupled coils. The voltage induced in the secondary coil is the sum of the individual voltages induced by the primary current and by the primary image current. This means that for constant values of M_{12} and M_{12}'

$$E_2 = j\omega I_1(M_{12}-M_{12}') = E_{12}-E_{12}' \qquad (1)$$

Thus to find the voltage E_2 induced in the secondary coil, it is necessary to evaluate M_{12} and M_{12}'. From the geometry of the situation and from electromagnetic theory, it is found[2] that for multiturn windings

$$M = \sqrt{Aa}\,n_1 n_2 4\pi y \times 10^{-9} \text{ henrys} \qquad (2)$$

(A and a are measured in centimeters, since the equation was derived using centimeter-gram-second electromagnetic units.)

Values of $4\pi y$ have been tabulated[3] in terms which may be expressed as a function of a/A and x/A. Since the tabulated values are somewhat inconvenient to use directly, curves of $M/\sqrt{Aa}$ versus x/A with the family parameter a/A were plotted as shown in Fig. 3. The curves are dimensionless in the abscissa (x/A) and the family parameter (a/A).

LINEARITY

In many applications, it is desirable that E_2 in equation 1 be at least approximately a linear function of displacement. Since the primary and secondary coils are supported on a probe structure, so that they are fixed in position relative to each other, the value of M_{12} will be constant. On the other hand, M_{12}' is a variable function of the separation between the secondary coil and the image coil. The linearity of M_{12}' is therefore the consideration which determines the linearity of E_2.

There is no finite range of any of the curves in Fig. 3 in which the curve is strictly linear. However, portions of these curves can be found which do not depart from strict linearity by more than some arbitrarily defined quantity. As will be seen later, the choice of a zero (or reference) point (used in defining a range of linearity) for practical mutual-inductance curves is optional and is determined by the specific application. Accordingly, the range of linearity is defined herein so as to be independent of the origin of the co-ordinates.

Therefore, departure from linearity in the neighborhood of a reference point x_0 (see Fig. 4) will be defined in terms of the ratio:

$$\eta = \left|\frac{\overline{PQ}}{\overline{QR}}\right| = \frac{|\Delta F(x)-\Delta G(x)|}{|\Delta G(x)|} \qquad (3)$$

where $F(x)$ is the curve and $G(x)$ the equation of a straight line tangent at x_0. Then a "range of linearity" is a range of values of x throughout which η remains less than a preassigned value.

$$F(x) \doteq F(x_0)+(x-x_0)\frac{F'(x_0)+F'(x)}{2} \qquad (4)$$

Also

$$G(x) = F(x_0)+(x-x_0)F'(x_0) \qquad (5)$$

By substituting values of $F(x)$ and $G(x)$ from equations 4 and 5, the desired range of linearity from $x=x_1$ to $x=x_2$ corresponds to x_1 in the equation

$$F'(x_1) = (1\pm 2\eta)F'(x_0) \qquad (6)$$

and to x_2 in the similar equation

$$F'(x_2) = (1\pm 2\eta)F'(x_0) \qquad (6A)$$

From curves of $F'(x)$ versus x (available in Fig. 5) it is possible to read the values of x_1 and x_2 corresponding to $F'(x_1)$ and $F'(x_2)$ computed from equations 6 and 6(A). The derivative curve in the neighborhood of $x=x_0$ will make it apparent whether the plus or minus sign should be used in equation 6 and 6(A). The curves in Fig. 5 make it apparent that the greatest range of linearity for any particular curve occurs when x_0 is chosen so that

$$F'(x_0) = \frac{F'(x_i)}{1+\eta} \qquad (6B)$$

where x_i = the value of x at the point of inflection. There are two such values of x_0, one on either side of the inflection point.

INDUCTANCE SENSITIVITY

These derivative curves are intimately related to sensitivity since

$$S_m=\frac{dM}{dx}=n_1n_2\sqrt{\frac{a}{A}}\frac{d\left(\frac{M}{\sqrt{Aa}}\right)}{d\left(\frac{x}{A}\right)}$$

$$=n_1n_2\sqrt{\frac{a}{A}}\text{ (ordinate of Fig. 5)} \qquad (7)$$

The maximum obtainable inductance sensitivity is not a function of A, so long as the ratio a/A is held constant. Also, for given values of x and a/A there is a value of A which will give greatest sensitivity. Table III shows ranges of linearity average sensitivity for $\eta=0.05$. It is apparent in Table III that increasing the range of linearity by reducing the ratio a/A entails a concomitant loss of sensitivity.

The effect of the conducting plate upon a coil system can be determined by substituting an image coil and current for the plate, and calculating the result with the aid of the equations and curves indicated in the foregoing. This situation is represented in Fig. 6 for zero current in the secondary coil. A typical gauge curve that results from calculating the effect of variable position of the metal plate is shown in Fig. 7.

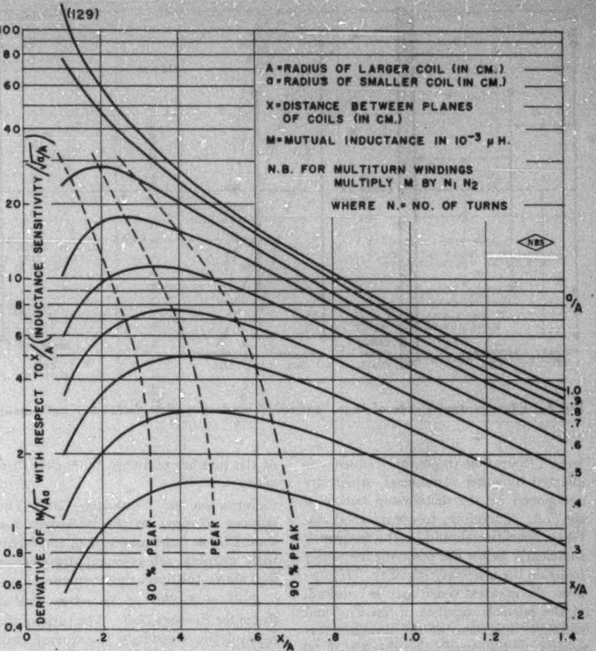


Fig. 5. Derivative of mutual inductance between two single-turn coaxial coils versus displacement between them

Design Recommendations

In view of the foregoing, certain design recommendations for obtaining optimum combinations of stability, sensitivity, and linearity are made.

Conductivity of the Plate: The material of the plate should have as high a conductivity as practicable. The plate will then more nearly simulate a perfect conductor, and the design curves (Figs. 3 and 5) will apply with a greater degree of reliability.

Relative Size of Primary and Secondary Coils: The primary coil should be the larger in order to provide greater heat-radiating surface, when the coils differ in size.

Position of Primary and Secondary Coils: From the point of view of sensitivity, the primary and secondary coils should be coplanar. However, if they are not coplanar, the primary coil should be the one farther from the plate so that the plate will have less effect upon the primary current.

Excitation Frequency: The excitation frequency should be as high as is consistent with avoiding the instabilities of resonance since the output increases with higher operating frequency. Also, a high excitation frequency decreases the depth of eddy-current penetration; hence the plate more nearly simulates a perfect conductor (zero depth of penetration).

In using as high a frequency as possible, however, the adverse effects of the unavoidable self-capacitance of the coils and their leads must be considered. Operation near the lowest self-resonant frequency is to be avoided because the output voltage is then a critical function of the exciting frequency and of the effective Q of the system. The Q itself is a critical function of the material, temperature, and mechanical dimensions of both the system and the surrounding ob-

Table III. Ranges of Linearity (Within 5 Per Cent) of the Static Mutual-Inductance Curves (Fig. 3)

	Range of Linearity				Average Inductance Sensitivity in this Linear Range (Equation 7) $\frac{\Delta M}{\Delta x}=\frac{\Delta M/\sqrt{Aa}}{\Delta x/A}\sqrt{a/A}$ (in 10^{-9} Henrys per Centimeter)

0.2	0.33	0.68	0.35	1.5– 1.0	0.64

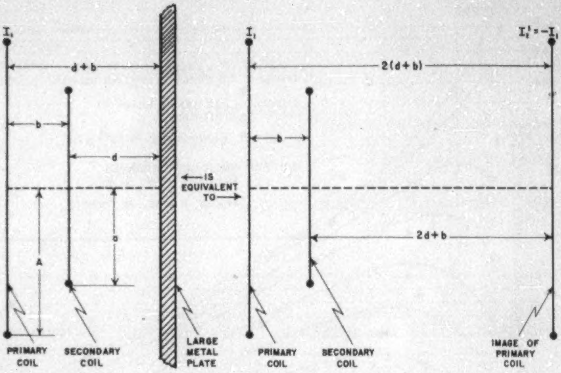

Fig. 6. Effective equivalence of large "perfectly" conducting plate (secondary coil open)

jects. Operation above this frequency is affected by other resonances, which are occasioned by the distributed nature of the coil. Therefore, to obtain good stability, operation should be at a frequency sufficiently below the resonant frequency to attain the necessary stability. If however, the greatest sensitivity is required, at the possible sacrifice of linearity and stability, operation at the resonant frequency is indicated. Sensitivity of 30 to 40 times the values calculated without considering resonance, have been obtained in this manner.

The actual value of self-capacitance is not easily predicted theoretically, since it depends upon the dielectric constants of the coil form and the wire insulation, and upon the specific manner in which the coil is wound. An indication of the value of this capacitance may be obtained from references 3 and 4.

Shielding of Leads: The leads to the primary coil should either be shielded from those of the secondary coil or be relatively fixed in position with respect to them. Undesired change in coupling would tend to mask the desired change in effective mutual inductance. It should be noted that the capacitance due to the shield will lower the self-resonant frequency.

Ampere-Turns of the Primary Coil: The ampere-turns of the primary coil should be as large as possible, since the output is proportional to this product. It is readily shown[5,6] that for a given allowable energy dissipation, coil volume and shape, frequency, material, etc., the maximum value of ampere-turns does not depend upon either the current or the number of turns, but upon their product.

Turns on the Secondary Coil: The number of turns on the secondary coil should be as large as possible, consistent with keeping self-resonant frequencies well above the operating frequency.

Ratio of Radius of Secondary Coil to that of the Primary Coil: The ratio of the radii of the secondary to primary coils (a/A) should be close to unity for relatively high sensitivity. Reference to Table III and Fig. 5 indicates this directly. As the sensitivity increases because of an increase in the ratio a/A, there is a corresponding but relatively small decrease in the range of linearity and inward change of its position.

Size of Primary Coil: The range of linearity increases as the radius of the primary coil increases for a constant value of a/A. This is the principal method of extending the range of linearity. Also, a larger primary coil has better heat-dissipating properties than a small one; however, the power requirement will be larger.

A larger primary coil radius may be accompanied by increased or decreased output voltage sensitivity (voltage change per unit displacement) depending upon what other changes in dimensions take place with the increase in coil radius. The analysis in Appendix I shows that if all linear dimensions of the probe system are increased by a scale factor h, then

$$S_e \doteq h^{\frac{1}{2}} S_e \tag{8}$$

where S_e is the voltage sensitivity of the scaled system. On the other hand, if A, a, and x are increased by a factor h, but the wire size and coil cross sections are kept unchanged, then

$$S_e' \doteq \frac{1}{h^{\frac{1}{2}}} S_e \tag{9}$$

(This particular result applies when the skin depth is small compared to the wire radius.) Thus in the one case voltage sensitivity is increased; in the other, decreased.

A probe with a large primary coil radius can be made to have a very high sensitivity. The curves shown in Fig. 5 indicate that the inductance sensitivity increases without limit as $(a/A) \rightarrow 1$ and $x/A(=2d+b/A) \rightarrow 0$. For a large A, a/A can be made to approach unity since the structural limitations on reaching this limit such as insulation thickness, minimum wire size, etc., are nearly constant, and hence represent smaller proportions of A. For the same reasons x/A can be made to approach zero.

Despite these considerations and possibly those of convenience and feasibility, the maximum coil size is limited by the

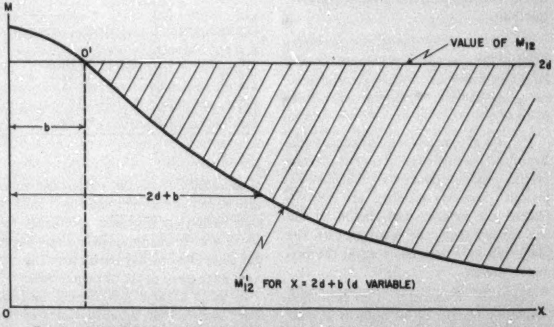

Fig. 7. Mutual-inductance curve showing effect of large perfectly conducting plate

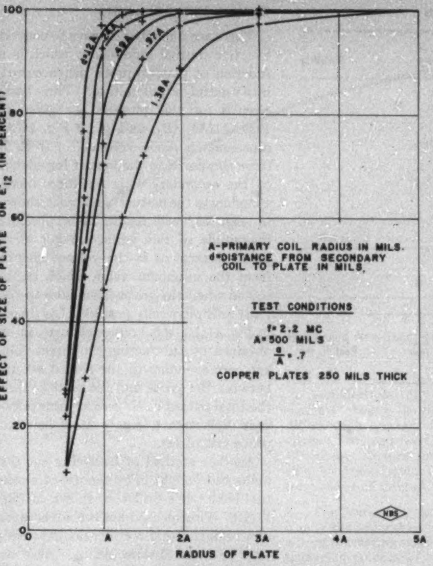

Fig. 8. Effect of finite plate size

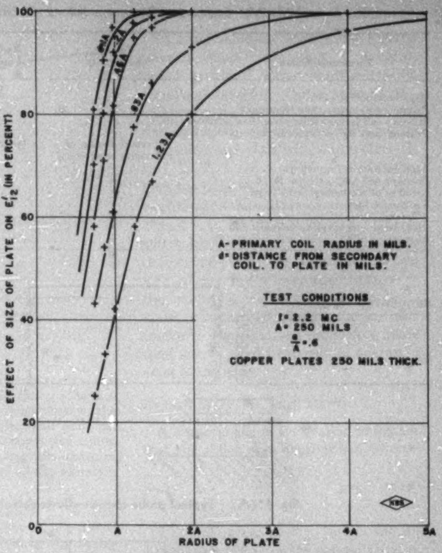

Fig. 9. Effect of finite plate size

extent of the plate. Theoretical considerations indicate that an actual plate has somewhat less effect than that calculated for an infinite plate. For a fixed percentage reduction in effect, the size plate required is a function of the distance between the coil system and the plate. Inserting the coefficient Γ in equation 1 to represent the effect of a finite plate

$$E = E_{12} - \Gamma E_{12}' \qquad (10)$$

represents the output voltage from a probe in the proximity of a perfectly conducting plate of limited size.

Theoretical calculations have not been carried to completion, but the results of two experimental cases giving the change in output due to a plate of limited size as a percentage of the change in output due to a plate six times the size of the larger (primary) coil are shown in Figs. 8 and 9 for different distances between the coils and the plate. These values apply for coplanar coils whose ratios, a/A, are 0.6 and 0.7 and do not necessarily apply for coils where a/A is widely different from these values, or where the coils are not coplanar. It appears that, in general, the greater the separation between coils and plate, the larger the plate necessary for a given effect.

Regulation of $I\omega$: The product $I\omega$ of the exciting frequency and the exciting current should be regulated to a constant value for stability of output. This follows directly from equation 1. Regulation of this product involves little difficulty. It can be attained by maintaining a constant (open-circuit) voltage across the secondary winding of an auxiliary transformer whose primary is excited by the current I_1. This is shown in Fig. 10.

General Discussion of Recommendations: Obviously, all of the recommendations cannot be satisfied simultaneously. Compromises must be made in accordance with the results desired. Table IV summarizes the effect of the recommendations on voltage sensitivity, range of linearity, and stability. A tendency to increase is designated by a (+) sign and a tendency to decrease is indicated by a (−) sign.

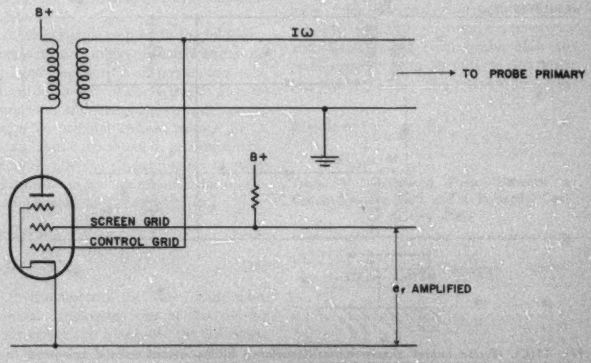

Fig. 10. Basic regulating circuit

Table IV. Summary of Recommendations and Effects

Recommendation	Voltage Sensitivity	Range of Linearity	Stability
High conductive plate	+		
Primary coil larger than secondary			+
Primary coil farther from plate than secondary coil			+
Primary and secondary coils coplanar	+ (beyond region of maximum sensitivity)	+ (generally)	
High excitation frequency	+		−
Primary coil ampere-turns large	+		
Number of secondary turns large	+		−
Ratio a/A high	+	−	
A large	±	+	
Plate large compared to primary coil	+		
Regulation of $I\omega$	+		+

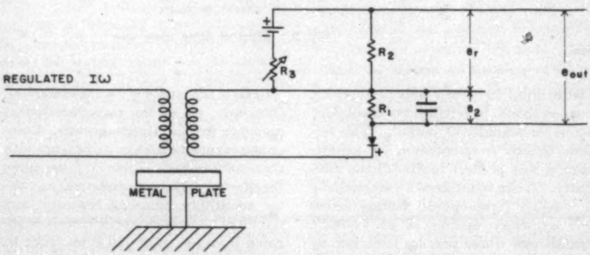

Fig. 11(B). Probe output circuit—diode detector with variable reference for output voltage

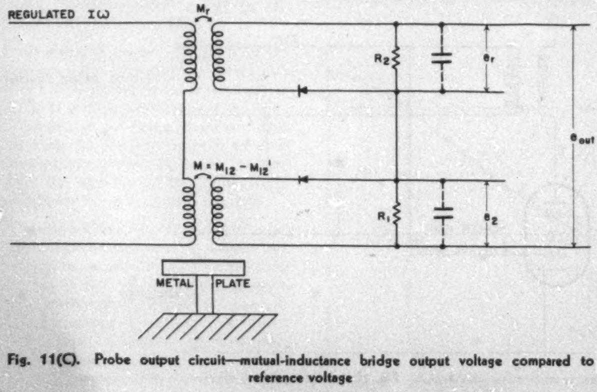

Fig. 11(C). Probe output circuit—mutual-inductance bridge output voltage compared to reference voltage

TYPICAL PROBE CIRCUITS

There are a number of ways to convert effective mutual inductance, which is a function of plate-to-probe displacement, into a useful output voltage. Three basic circuits for this purpose are given in Figs. 11(A), (B), and (C). Fig. 11(A) represents a diode voltmeter. If R_1 is large compared to the output impedance of the secondary coil, a voltage corresponding to the mutual inductance, shown in Fig. 12, will result. The absolute magnitude of this voltage is not of as much interest as is the voltage change from the minimum value which is obtained when the probe is as close to the plate as is physically possible. As shown in Fig. 11(B), this voltage change can be obtained by subtracting the direct voltage corresponding to the closest setting between the probe and the plate so that the total output e_{out} is zero at some reference diplacement (e.g., contact between probe and plate).

Another method of balancing out the undesired voltage is by the use of a mutual-inductance bridge as shown in Fig. 11(C). This method has the advantages of a bridge in that rectifier nonlinearities may be offset to some extent. Also the mutual inductance of the comparison coils may be changed to produce a balance.

The voltage output e_r from the comparison or reference coil of fixed mutual-inductance M_r may be used to control the value of the product $I\omega$ by appropriate feedback. Such a scheme is indicated in Fig. 10. Here, the voltage on the screen grid of a pentode oscillator is varied in accordance with the variations of the reference output voltage e_r. Complete circuits, showing regulation and buckout schemes as described, are given in references 7, 8, and 9.

FORCE ON PLATE DUE TO THE PRIMARY CURRENT

In some applications it is necessary to consider the effect of electromechanical forces on the plate resulting from the presence of the probe. As will be seen, these forces are rather small. There will be no effect because of the presence of the secondary coil since there is no current through this coil.

The force on the primary coil resulting from the presence of a large perfectly conducting plate is the same as that resulting from the image coil. Since "action equals reaction," this force is the same in magnitude as the total force on the plate. Since the current in the image coil is opposite in direction to that of the primary coil, the force is one of repulsion.

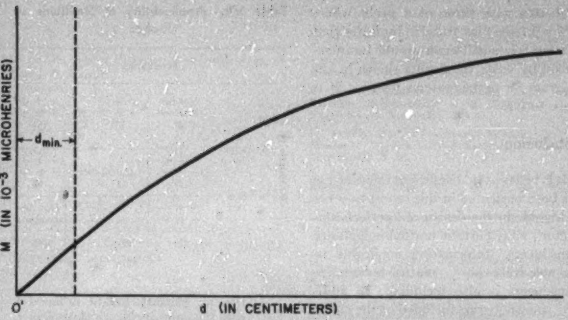

Fig. 12. Effective mutual inductance versus distance d from secondary coil to plate

An equation for evaluating the force[5] between a coil and its image is

$$F=-n_1^2 i_1^2 \frac{dM}{dx} 10^{-11} \tag{11}$$

Here x is the distances between the primary coil and its image, or twice the distance from the primary coil to the plate. If the axis of the primary coil is perpendicular to the plate, dM/dx becomes the ordinate shown in Fig. 5 for the curve $(a/A)=1$.

Several typical values of force corresponding to values of i_1, n_1, and x/A are given in Table V to show the order of magnitude of the force involved. This equation applies to the case of a perfectly conducting plate, infinite in extent. The size limitations of a practical plate will decrease the force below this value; finite resistivity of the plate will also reduce the force.

GAUGES FOR DYNAMIC MEASUREMENTS

In the previous sections changes in mutual inductance were considered as a function of a static configuration. If there is a relative motion, the probe output will be a function of the rate of change of mutual inductance with respect to time (dM/dt) as well as of the rate of change of current with respect to time (dI/dt). That is

$$e=\frac{d(MI)}{dt}=M\frac{dI}{dt}+I\frac{dM}{dt} \tag{12}$$

An analysis of the effect of this motion shows that the effect is similar (but not identical) to amplitude modulation. There is no error in using static considerations if the following conditions are met:

1. The frequency of the exciting current is higher than the highest frequency component of the mechanical vibration.
2. The bandwidth of the circuits which pass the carrier or exciting frequency and its modifications due to the mechanical motions should be flat from below the difference frequency of electrical and mechanical frequencies to above their sum. Of course, circuits following the detector (if any) should be flat over all the vibration frequencies of interest.
3. The equivalent amplitude modulation should not be increased beyond 100 per cent when subtracting carrier voltage by bridge balancing processes.

Application of Electrodynamic Similitude Principles to Gauge Development

In the preceding sections no methods were indicated for predicting the effects of reference plates of types different from extensive perfect conductors. No general theory which will enable prediction of these effects has been found in this investigation. However, it is often possible to obtain the desired prediction from tests on an appropriate scaled model by use of the principle of electrodynamic similitude.

That principle as used in the following means that in a given electric circuit or coil configuration, if all parameters of a given dimension (such as length or conductivity) are changed by a scale factor, then the original output voltage for a given input current can be maintained by properly altering all parameters of other dimensions in accordance with the dimensional equations 13 and 14[10]

$$\mu\epsilon(fL)^2=C_1 \tag{13}$$

$$\mu\sigma fL^2=C_2 \tag{14}$$

In the material to follow, while more general conclusions can be derived by considering μ as a variable, the discussion will be confined to nonferromagnetic materials where the μ is constant.

SCALING FROM EXPERIMENTAL RESULTS

In a mutual-inductance probe, a given primary current will result in a corresponding voltage output which will be the same both before and after scale modifications on the probe. If either the design or experimental curves for a model transducer and plate with parameters A, a, d, b, R, t, σ, and f are available, then the same magnitudes of E and I will be obtained if the scaled system has parameters hA, ha, hd, hb, hR, ht, σ/h, and f/h, where h is the scaling factor, R the plate radius, and t the plate thickness. When $h>1$, a larger probe is required to increase the operating distances, and the plate must be correspondingly larger and thicker. The electrical quantities, plate conductivity, and frequency of operation must be reduced.

EFFECT OF FINITE SKIN DEPTH

A consequence of the scaling process is that the scaled skin depth is h, δ, where[11]

$$\delta=\sqrt{\frac{C_2}{\mu\sigma f}} \tag{15}$$

The scaling was used to justify the dimensionless form for the presentation of the experimental measurements of the effects of limited plate size in Figs. 8 and 9.

Another example of the conclusions that may be obtained by using the principle of similitude is the following: An empirical equation was obtained from a series of measurements at different frequencies which showed how the skin depth (in mils) modified the output of a probe system. The measurements were made with a probe coil whose primary coil radius was 500 mils, secondary coil radius 350 mils (i.e., $a/A=0.7$), frequencies ranging from 100 kc to 1 megacycle, a large thick circular copper plate of resistivity (ρ) 2.16 microhm-centimeters, and displacement from probe coils to plate ranging from 50 mils to 850 mils ($0.1 \leq d/A \leq 1.7$). The relation found is

$$E_2=E_{12}-\frac{1}{1+0.0066\delta}E_{12}' \tag{16}$$

Table V. Calculated Force Between a Current-Carrying Coil and a Perfectly Conducting Plate

$\frac{x}{A}$	$\frac{d+b}{A}$	n	i, Amperes	F, Dynes
0.1	0.05	12	1	−185
0.1	0.1	12	1	− 95.5
0.4	0.2	12	1	− 40.0
1.0	0.5	12	1	− 10.8
2.0	1.0	12	1	− 2.18

1 ounce≐27,800 dynes.

Table VI. Percentage Reduction from Maximum Value of E_{12}' when $a/A=0.7$ and $0.1 \leq d/A \leq 1.7$

Frequency	Material	Skin Depth, Mils	Per-Cent Reduction in E_{12}'
100 kc	copper	9.2	5.7
100 kc	brass	16.8	10.0
1 megacycle	copper	2.91	1.9
1 megacycle	brass	5.3	3.4

An additional series of experiments with a corresponding brass plate ($\rho=7.17$ microhm-centimeters), using the same probe, range of frequencies, and range of displacements, was found to be a close approximation by the same relation 16.

Equation 16 indicates that the effective E_{12}' is less than E_{12} by a percentage depending upon δ in the experiments. This percentage reduction is tabulated in Table VI for copper and brass at the two extreme frequencies used in the experiments. It appears reasonable that for the given probe and a given frequency, the relation 16 applied over a continuous range of conductivities from that of copper to that of brass and gives a monotonic variation in the percent reduction in E_{12}' over this range of conductivities.

By application of similitude, any probe having $a/A=0.7$ operating at any frequency in the neighborhood of an extensive thick plate of any conductivity can be scaled to a probe whose primary coil radius is 500 mils, and to a corresponding frequency and plate conductivity. The converted frequency and conductivity will fall into one of four main groups:

1. Both fall within their respective limits in the experiments. Per-cent reduction of E_{12}' of original system can be calculated.
2. Only one falls within the range of the experimental limits. An upper or lower limit on the per-cent reduction of E_{12}' can be calculated from the experimental data referred to in item 1 as indicated in Table VII.
3. Both fall outside the range of experimental limits in a manner such that each tends to have an effect in the same direction on the per-cent reduction in E_{12}'. Per-cent reduction in E_{12}' is less than 1.9 per cent or greater than 10 per cent.
4. Both fall outside the range of experimental limits in a manner such that each tends to have an effect in opposite directions on the per-cent reduction in E_{12}'. The per-cent reduction in E_{12}' cannot be predicted without additional information.

The effect of the four groups is shown in Table VII.

Although the experiments and resulting inferences apply to probes with a ratio $a/A=0.7$, a comparison of the experimental results with a probe where $a/A=0.6$ with those of a probe where $a/A=0.7$(see Figs. 8 and 9) indicates that a relatively small error would be introduced by using the results shown in the diagram for probe systems whose a/A is close to 0.7.

Conclusion

It is believed that sufficient information has been presented in this report to serve as a guide in the design of "perfect-conductor" eddy-current mutual-inductance transducers. Information applicable to movable-coil-type mutual-inductance transducers is also included. In addition, some notes are included on the modifications that will occur when resistive plates are used. An indication is given of how to determine when the errors, made by applying perfect-conductor results to practical resistive conductors, are small.

Although a method of scaling experimental models is mentioned, the information on eddy-current mutual-inductance transducers when used with resistive plates is incomplete. Also, no information on ferromagnetic plates is given. The theoretical prediction of results for these cases does not appear to be available. The solution of this problem would be of value in many problems that require the use of resistive conductors. These include the determination of the position of a thin diaphragm, or of the top of a column of mercury, problems in the field of induction heating, and the measurement of the electrical properties of alloys for such purposes as inspection, the determination of hardness, or the thickness of plated metal film.

Appendix I. Voltage Sensitivity Versus Primary Coil Radius

The voltage sensitivity is affected differently by an increase in primary coil radius depending upon whether or not the wire size and coil cross sections are correspondingly increased. In both cases to be discussed, it will be assumed that A, a, b, and d of the probe configuration are multiplied by a factor h (greater than unity).

The following symbols and associated meanings will be used:

I = maximum permissible current in the primary coil for a fixed temperature rise
I' = maximum permissible current in the primary coil of radius hA for the same temperature rise
ω = maximum angular frequency of excitation for primary coil of radius consistent with avoiding resonance effects
ω' = maximum angular frequency of excitation for primary coil of radius hA with the same avoidance of resonance effects
α = ratio of a-c resistance to d-c resistance in the primary coil
P = power dissipated in primary coil
A_r = heat-radiating area of primary coil
R = total d-c resistance of primary coil
s = total length of wire in the primary coil
d = diameter of wire of the primary coil
S_e = voltage sensitivity
S_e', P', A_r', R', s', d', and α' will have corresponding meanings for the primary coil when modified, as indicated.

Table VII. Applicability of Similitude to Probes

Conductivity	Frequency		
	Not determined (4)	+ + + + + + .N (2) .N′	+ + + + + + (3)
σ copper			
	− − − − − − (2)	Calculable (1)	+ + + + + + (2)
σ brass			
	− − − − − − − − − (3)	− − − − − − − − − (2)	Not determined (4)
		100 kc	1 mc

As a first case, assume all linear dimensions of the coil system are multiplied by a factor h. A fixed temperature rise means that

$$\frac{P'}{A_r'}=\frac{P}{A_r} \tag{17}$$

Substituting resistive losses for P's

$$I'=h^{(3/2)}I\sqrt{\frac{\alpha}{\alpha'}} \tag{18}$$

Since the self-inductance and self-capacitance of a coil each vary with the average radius of the coil[13]

$$L'C'=h^2LC \tag{19}$$

Hence

$$\omega'=\frac{\omega}{h} \tag{20}$$

From equation 1

$$S_e=I\omega\frac{dM}{dx} \tag{21}$$

and, as dM/dx is independent of A for a given a/A and x/A as previously noted, S_e is proportional to $I\omega$. Therefore, from equations 18 and 20

$$S_e'=h^{1/2}S_e\sqrt{\frac{\alpha}{\alpha'}}=h^{1/2}S_e \tag{22}$$

Since all linear dimensions and frequency have been scaled, $\alpha'=\alpha$ (reference 13); thus the voltage sensitivity rises as A increases (under these assumed conditions).

As a second case, assume the wire size and coil cross sections remain unchanged while A, a, b, and d are increased by a factor h, as in the first case. Equation 19 is approximately true for this case. Then

$$I' \doteq I\sqrt{\frac{\alpha}{\alpha'}} \tag{23}$$

since the power dissipated per unit area of coil is constant.

Now[13]

$$\omega' \doteq \frac{\omega}{h} \tag{24}$$

Then

$$S_e' \doteq \frac{S_e}{h}\sqrt{\frac{\alpha}{\alpha}} = \frac{S_e}{h^{\frac{1}{2}}} \tag{25}$$

since case $\alpha' \doteq (1/h)\alpha$, when $\delta<<A$ (reference 13). Thus the voltage sensitivity drops as A increases.

A Fast Response Magnetic Servo Amplifier

J. W. KALLANDER
ASSOCIATE MEMBER AIEE

IN SERVOMECHANISMS used in military applications, one of the weakest links is the electronic amplifier. The electronic amplifier is undesirable primarily because of its fragility, maintenance requirements, low power efficiency, and often objectionable warm-up time. The magnetic amplifier is much more rugged, has a much longer life, has a greater power efficiency, requires much less maintenance, and has no warm-up time. Thus, one of the most obvious and potentially fruitful applications of magnetic amplifiers is in the control of 2-phase motors in servomechanisms.

Although the magnetic amplifier field made tremendous strides after World War II, the inherently long time delay of the magnetic amplifier seriously limited its applications to servomechanisms until the invention of the "half-cycle response time" magnetic amplifier[1,2] several years ago. This magnetic amplifier has a time delay of from 1/2 to 1 cycle of the supply frequency for full output, i.e., 0.0083 to 0.0167 second for a 60-cycle amplifier or 0.0012 to 0.0025 second for a 400-cycle amplifier, which is sufficient for many servo applications.

Since that time only one half-cycle response time magnetic servo amplifier[3] has been described in the literature. Consequently, it is believed that additional magnetic servo amplifiers of the half-cycle type will find useful applications. Thus, it is the purpose of this report to describe the theory and operation of a new magnetic servo amplifier.

The following major conditions have been used as a guide in deducing these circuits:

1. The output of the magnetic amplifier must contain a phase-reversible a-c component of the fundamental frequency capable of controlling a 2-phase motor.

2. The input circuit must be sensitive to a phase-reversible a-c signal of the fundamental frequency or to a reversible-polarity d-c signal.

3. The amplifier must have a fast response time, preferably 1/2 cycle.

4. The amplifier must be capable of driving the servomotor and load, i.e., must meet their power requirements and must be able to operate into the back electromotive force of the motor.

5. The amplifier should be capable of presenting a high impedance to the input signal source.

Nomenclature

e_{ac} = gating-circuit supply voltage
e_{ac}' = control-circuit supply voltage
e_c = control voltage
R_c = control-circuit resistor
ϕ_c = control phase of 2-phase servomotor
N = ratio of gating-winding turns to reset (control)-winding turns
N_g = number of gating-winding turns
N_c = number of reset (control)-winding turns
ωt = radians
ω = angular velocity, radians per second
B = flux density
Ni = magnetomotive force
k = ratio of control-circuit supply voltage e_{ac}' to gating-circuit supply voltage referred to the control circuit e_{ac}/N
α = quiescent firing angle
e = reset (control)-winding voltage
e_{I} = core I reset (control)-winding voltage
e_{II} = core II reset (control)-winding voltage
e_R = control-resistor voltage
$e_{R\mathrm{I}}$ = core I control-resistor voltage
$e_{R\mathrm{II}}$ = core II control-resistor voltage
I_m = maximum magnitude of the reset-circuit magnetizing current
E_R = product of the maximum magnitude of the reset-circuit magnetizing current I_m and the control resistor R_c
L = magnitude of the maximum volt-second integral, referenced to the reset (control)-winding, available for application to a core during its gating half-cycle (ghc)
Δe = change in the reset (control)-winding voltage caused by the control voltage
Δ = integral of Δe over the reset half-cycle (rhc)
i_m = control-circuit magnetizing current

Description of Circuits

All magnetic cores used in the circuits described in this paper are of the so-called

Paper 55-57, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted June 14, 1954; made available for printing November 29, 1954.

J. W. KALLANDER is with the Naval Research Laboratory, Washington, D. C.

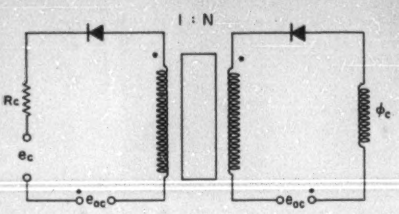

Fig. 1. Ramey single-core magnetic amplifier

"square loop" core material. The convention of indicating square-loop core material by means of a rectangle drawn between the windings on a core has been adopted in the circuit diagrams. The ends of the windings on a core having the same instantaneous polarity are dotted. This convention applies to the cores individually and does not indicate their relative polarities. The ends of transformer windings having the same instantaneous polarity are also dotted. In this case, the dotted ends of all transformer windings in a circuit have the same instantaneous polarity.

RAMEY SINGLE-CORE MAGNETIC AMPLIFIER

The Ramey single-core magnetic amplifier,[1,3] Fig. 1, is a very simple magnetic amplifier which meets the response-time and output rating conditions of the preceding section. One single-core amplifier is sensitive to an a-c control signal within a given 180-degree phase range or to a d-c control signal of a given polarity, yielding an output which will drive a 2-phase servomotor in a given direction; in the same circuit, a control signal of the opposite 180-degree phase range or polarity yields no output. A second single-core amplifier can be made sensitive to a control signal of the opposite 180-degree phase range or of the opposite polarity, yielding an output of the phase which will drive the 2-phase motor in the direction opposite to that of the first single core amplifier. Again, the second single-core amplifier does not respond to a control signal of the 180-degree phase range or polarity opposite to that for which it was designed. Thus, a combination of two single-core magnetic amplifier should also satisfy the reversible input and output conditions, forming a magnetic servo amplifier which meets the first four conditions imposed in the foregoing.

Two single-core amplifiers, each with half-wave output, can be combined to fire on alternate half-cycles, thus giving a unidirectional output.[4] A Fourier analysis of such an output wave shows no fundamental frequency component when both cores are firing at the same angle during their respective gating half-cycles. Thus, the amplifier can be biased to give a quiescent output current in which the outputs on consecutive half-cycles are equal.

The output-voltage wave shape of such an amplifier biased to fire at 90 degrees in its quiescent state is shown in Fig. 2(A). The solid lines give the amplifier output voltage; the dashed lines indicate the supply voltage rectified. As already stated, the quiescent output has no fundamental frequency component; hence, no net output torque would be supplied by a 2-phase servomotor excited by such an output. Fig. 2(B) shows the output wave form for a control signal of a given 180-degree phase range or of a given polarity. The output of one core, say core I, has been advanced to a firing angle of β while the output of the other core, say core II, has been retarded to a firing angle of $(\pi-\beta)$ on its ghc. The output will now have a fundamental frequency component. Fig. 2(C) gives the output wave shape for a control signal of the opposite 180-degree phase range or of the opposite polarity. The output of core I is now retarded to a firing angle of β while the output of core II is advanced to a firing angle of $(\pi-\beta)$ on its ghc. The output, now has a fundamental frequency component of the opposite phase to that of Fig. 2(B).

A Fourier analysis of the output gives the ratio of the fundamental frequency output component to the supply voltage as

$$\frac{b_1}{E}=\frac{1}{\pi}\left(\frac{\pi}{2}-\beta+(1/2)\sin 2\beta\right) \qquad (1)$$

in phase with the supply voltage. Fig. 3 gives the variation of b_1/E with the firing angle β of the first core.

It is advantageous to bias an amplifier in this manner to decrease or nullify completely the variation in phase of the fundamental frequency component as its magnitude is varied, to furnish a quiescent output damping current, and to realize increased gain. In the case discussed, i.e., a quiescent firing angle of 90 degrees, the phase of the fundamental frequency

component of the output is constant and is in phase, or 180 degrees out of phase, with the supply voltage.

NEW MAGNETIC SERVO AMPLIFIER—A-C CONTROL

One means of combining two single-core amplifiers in a manner satisfactory for 2-phase servomotor operation is given in Fig. 4. This circuit consists essentially of two single-core amplifiers connected in parallel across a common signal source and a common load, as shown. The load circuit of the amplifier so obtained is the same as that of a magnetic servo amplifier described by W. Geyger.[4] Geyger[5] has recently described another magnetic servo amplifier in which the control circuit, rather than the load circuit, closely resembles the amplifier described here. In the Ramey single-core amplifier, $e_{ac}'=e_{ac}/N$ and the control resistor R_c is absent or small, furnishing a quiescent output current if desired. This circuit with the two single-core amplifiers unaltered is satisfactory for signal sources of low output impedance requiring a low impedance load. The circuit, however, is unsatisfactory for operation with a high impedance in the control circuit, such as required by a synchro control transformer, because the large impedance would absorb most, if not all, of the control-circuit supply voltage on the rhc, leaving little if any, voltage for the reset winding. Thus, the amplifier would only partially reset, if at all, on the rhc. This limitation can be removed by increasing the control-circuit supply voltage e_{ac}' from e_{ac}/N to ke_{ac}/N where $k>1$. In addition, on the ghc, when the control voltage is adding to the control-circuit winding voltage of the gating core, a control voltage of $e_{ac}'-e_{ac}/N$ is necessary before transformer action commences in this circuit. Thus, with $e_{ac}'=e_{ac}/N$, transformer action will take place for all e_c but, for $e_{ac}'=ke_{ac}/N$, transformer action will only occur when $e_c>(k-1)e_{ac}/N$. For no quiescent current

$$\int_{\text{rhc}} e_{ac}/N dt$$

must appear across the reset windings during their rhc. Thus, the value of k is determined from the following equation

$$\int_{\text{rhc}} i_m R_c dt=\int_{\text{rhc}}(k-1)e_{ac}/N dt,\ k\geq 1 \qquad (2)$$

where

i_m = the control-circuit magnetizing current
R_c = the control resistor determined by the minimum impedance required by the control source
N = the ratio of the gating-winding turns to the reset-winding turns
e_{ac} = the supply voltage in the gating circuit

If a quiescent current is desired, it can be obtained simply by increasing the value of the control resistors R_c above the value obtained in the preceding equation. Quantitatively, let α be the ratio of the desired average quiescent current on a half-cycle to the average of the maximum output current on a half-cycle, then the preceding equation for determining k can be modified to

$$\int_{\text{rhc}} i_m R_c dt=\int_{\text{rhc}}(k-1+\alpha)e_{ac}/N dt,$$
$$k\geq 1,\ 0\leq\alpha\leq 1 \qquad (3)$$

See equation 5 for an equivalent definition of α. When the control source has a high impedance R_s, R_c in the foregoing equations can be replaced by R_c+R_s.

It should be noted that the power dissipated in the control resistors is furnished by the control-circuit supply voltage. Thus, the voltage sensitivity can be made large, since the lower limit on the number of reset-winding turns is determined by practical considerations.

NEW MAGNETIC SERVO AMPLIFIER—D-C CONTROL

Fig. 4 can be changed into a d-c controlled circuit simply by reversing the sense in which one of the control circuits of the single-core amplifiers is paralleled across the signal source. This circuit is shown in Fig. 5. The foregoing symbols and equations are also valid for this circuit.

NEW MAGNETIC SERVO AMPLIFIER—IMPROVED GAIN

The characteristics of this circuit, when in operation, are such as to give effective hysteresis loops resembling those of Fig. 6 if perfectly rectangular hysteresis loops are assumed. Fig. 6(A) shows a typical quiescent-state loop with the core circling about half of its hysteresis loop. Figs. 6(B) and (C) show the steady-state hysteresis loops circled by the two cores of an amplifier when a given control signal is applied. The control signal hinders the reset of the core whose hysteresis loop is shown in Fig. 6(B), say core I, and aids the reset of the core whose hysteresis loop is shown in Fig. 6(C), say core II. The control-circuit current in Fig. 6(B) is decreased and that in Fig. 6(C) is increased. Thus, the core I control-resistor voltage drop will decrease, leaving a greater voltage drop across core I during reset than if the control-circuit current had remained constant. Thus, the control signal does not all appear across the reset winding but divides between the reset winding and the control resistor. Similarly, in core II, the control-voltage resistor drop increases so that the control signal divides between the reset winding and the control resistor instead of appearing solely across the reset winding. Thus, the gain of the new magnetic servo amplifier shown will decrease with increasing signal. This is because the control-circuit current and, hence, the control-resistor voltage drop on the reset half-cycles decrease as the core circles smaller and smaller hysteresis loops, and increase as the core circles larger and larger hysteresis loops.

The voltage drop across the control resistor can be prevented from decreasing appreciably by inserting a voltage source and rectifier across the control resistor, as shown in Fig. 7 for the a-c controlled

amplifier. They can be added to the d-c controlled amplifier in exactly the same manner with the same results. The voltage source is of the same frequency and phase as the supply voltages and of a magnitude equal to the magnitude of the quiescent-state control-resistor voltage drop. In the quiescent state, this voltage source furnishes no current but, as the magnetizing current decreases, tending to decrease the control-resistor voltage drop, this voltage source maintains the control-resistor current essentially constant, thereby maintaining the same voltage drop across the control resistor as in the quiescent state. Thus, on the rhc, most of the control-signal voltage appears across the reset winding.

Theoretical Analysis

The rectifier algebra of Schaefer[6] will be used to give a quantitative analysis of the new magnetic servo amplifier for an arbitrary signal-voltage wave form. The analysis will be based on the volt-second integral concept and depends on the fact that the output of the amplifier on any half-cycle depends solely on the signal voltage applied during the previous half-cycle. Perfectly square-loop cores, constant magnitude of the magnetizing current, and perfect rectifiers are assumed, and all resistance in the control circuit is included in the control resistors. The effect of the back electromotive force of the motor is not taken into account.

Fundamentally, rectifier algebra consists of six operations: addition, subtraction, multiplication, division, maximization, and minimization. The first four operations are defined and denoted as in ordinary algebra. Maximization is defined as the operation of comparing two algebraic quantities and selecting the maximum of the two. Minimization is defined as the operation of comparing two algebraic quantities and selecting the minimum of the two. They are denoted by the symbols $\vee$ and $\wedge$ respectively. $a \vee b$, read a max b, equals a if $a>b$ and b if $a<b$. Similarly $a \wedge b$, read a min b, equals a if $a<b$ and b if $a>b$. By use of these operations on algebraic quantities, the following rules (among others) have been derived

(A). $a \wedge b = -[(-a) \vee (-b)]$

(B). $a+(b \vee c) = (a+b) \vee (a+c)$

The circuit being analyzed and the symbols used are shown in Fig. 8. The positive direction of voltages is as shown. The circuit shown is that for a-c control. However, this analysis will apply equally well for the corresponding d-c controlled circuit for the corresponding signal voltage.

$e_c^{dc} = e_c^{ac}, \; 0 < \omega t < 180°$

$e_c^{dc} = -e_c^{ac}, \; 180° < \omega t < 360°$

Before particularizing to one of the cores, the symbols are used without the core I and II subscripts, i.e., e and e_R refer to the reset-winding and to the control-resistor voltages respectively of either core. In addition, I_m is the maximum magnitude of the reset-circuit magnetizing current; it is assumed constant. $E_R = I_m R_c$, a constant.

Define the magnitude of the maximum volt-second integral, referred to the reset winding, which can be applied to a core during its ghc.

$$L = -\int_{\text{ghc}} \frac{e_{ac}}{N}\,dt = \int_{\text{rhc}} \frac{e_{ac}}{N}\,dt \tag{4}$$

Define the measure of quiescent reset (not applicable to other than the quiescent state)

$$\alpha = \frac{\int_{\text{rhc}} \left(\frac{e_{ac}}{N} - e \right) dt}{L} = \frac{\int_{\text{rhc}} \left(e_R - \frac{k-1}{N} e_{ac} \right) dt}{\int_{\text{rhc}} \frac{e_{ac}}{N}\,dt} \tag{5}$$

where e and e_R are quiescent values $\alpha = 0$ corresponds to full reset, $\alpha = 1$ corresponds to no reset, with a linear relationship between intermediate values of α and intermediate resets.

Consider a control circuit. In the quiescent state during the rhc

$$e_R = e_{ac}' \wedge E_R \tag{6}$$

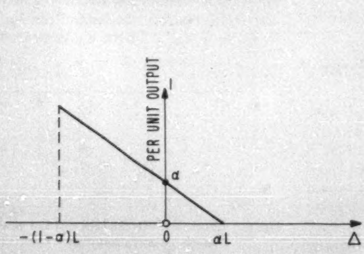

Fig. 9 (A) (left). Half-cycle output of new magnetic servo amplifier versus Δ

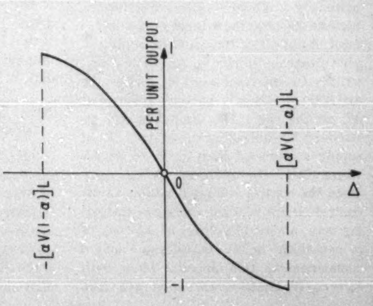
Fig. 9 (B) (right). Servo output of new magnetic servo amplifier versus Δ



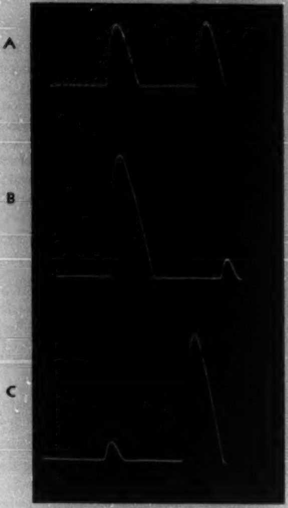


Fig. 10 (A). Steady-state quiescent output current oscillogram. (B) Steady-state output current oscillogram for a positive signal. (C). Steady-state output current oscillogram for a negative signal

$$e=e_{ac}'-e_R$$
$$=e_{ac}'-(e_{ac}'\wedge E_R) \qquad (7)$$

From rule (A)

$$e=e_{ac}'+[(-e_{ac}')\vee(-E_R)]$$

From rule (B)

$$e=0\vee(e_{ac}'-E_R)$$

But the gating circuit limits e to e_{ac}/N the rhc giving

$$e=[0\vee(e_{ac}'-E_R)]\wedge\frac{e_{ac}}{N} \qquad (8)$$

The volt-second integral received by the core during each rhc during the quiescent state is

$$\int_{\text{rhc}} edt=\frac{\int_{\text{rhc}}\frac{e_{ac}}{N}\,dt-\int_{\text{rhc}}\left(\frac{e_{ac}}{N}-e\right)dt}{L}\,L$$

$\int_{\text{rhc}} edt=(1-\alpha)\,L$ in the quiescent state. (9)

Now consider the operation of the amplifier with a control voltage e_c applied. Consider a control circuit during the rhc

$$e_R=(e_{ac}'-e_c)\wedge E_R \qquad (10)$$
$$e=(e_{ac}'-e_c)-[(e_{ac}'-e_c)\wedge E_R]$$

Using rules (A) and (B) just as was done in the quiescent state

$$e=0\vee(e_{ac}'-e_c-E_R)$$

from the control circuit. But the gating circuit still limits e to e_{ac}/N. Therefore

$$e=[0\vee(e_{ac}'-e_c-E_R)]\wedge\frac{e_{ac}}{N} \qquad (11)$$

Now consider the change in the reset-winding voltage caused by the control voltage

$$\Delta e=[0\vee(e_{ac}'-e_c-E_R)]\wedge\frac{e_{ac}}{N}-$$
$$[0\vee(e_{ac}'-E_R)]\wedge\frac{e_{ac}}{N} \qquad (12)$$

For the case where $(e_{ac}'-E_R)\le e_{ac}/N$ and $(e_{ac}'-e_c-E_m)\le e_{ac}/N$ at all times during the rhc, Δe can be simplified to

$$\Delta e=[0\vee(e_{ac}'-e_c-E_R)]-[0\vee(e_{ac}'-E_R)] \qquad (13)$$

The integral of this voltage change over the rhc determines the effect of the control signal on the next half-cycle. Designate this change in the reset voltage-time integral by Δ

$$\Delta=\int_{\text{rhc}}\Delta e dt \qquad (14)$$

$$\Delta=\int_{\text{rhc}}\left\{[0\vee(e_{ac}'-e_c-E_R)]\wedge\frac{e_{ac}}{N}-\right.$$
$$\left.[0\vee(e_{ac}'-E_R)]\wedge\frac{e_{ac}}{N}\right\}dt \qquad (15)$$

For the case where

$$(e_{ac}'-E_R)\le\frac{e_{ac}}{N}\text{ and }(e_{ac}'-e_c-E_R)<\frac{e_{ac}}{N}$$

throughout the rhc

$$\Delta=\int_{\text{rhc}}\{[0\vee(e_{ac}'-e_c-E_R)]-$$
$$[0\vee(e_{ac}'-E_R]\}dt \qquad (16)$$

It is this quantity Δ which when evaluated during one half-cycle determines the output of the amplifier on the following half-cycle.

Consider the quantitative effect of Δ on the following half-cycle. When $\Delta=0$, the amplifier will furnish its quiescent output on the following half-cycle. When $\Delta=-(1-\alpha)L$, the amplifier will furnish maximum output on the following half-cycle. When $\Delta=\alpha L$, the amplifier will furnish zero output on the following half-cycle. A linear relationship, determined by these points, exists between Δ and the amplifier output on the following half-cycle.

In considering the operation of the magnetic servo amplifier, it is the fundamental component of the output which is of interest. Thus, in considering an entire cycle, the quiescent output on both half-cycles will yield no fundamental output. Full output on the first half-cycle and zero output on the next half-cycle will yield maximum fundamental output. Zero output on the first half-cycle followed by maximum output on the next half-cycle will yield maximum reversed fundamental output.

Fig. 11. A transient output current oscillogram

The relationships between Δ and the half-cycle output is shown in Fig. 9(A). If it is assumed that Δ's equal in magnitude but opposite in sign are applied to the two cores on alternate half-cycles, Fig. 9(B) gives the form of the relationship between Δ and the fundamental output.

Description of Laboratory Circuit

Representative circuits of the magnetic servo amplifiers of Figs. 1, 4, 5, and 7 were constructed in the laboratory for a supply frequency of 60 cycles and satisfactorily operated 2-phase motors. Particular attention was paid to the circuit of Fig. 7 with the following components and parameters: Supply frequency of 60 cycles; Deltamax cores no. *5320-D1* with an inside diameter of 1.500 inches, an outside diameter of 2.500 inches, and height of 0.500 inch; $N_g=3{,}000$ turns no. 26 heavy Formvar; $N_c=60$ turns no. 26 heavy Formvar; $N=50$; $e_{ac}=115$ volts rms; $e_{ac}'=190$ volts rms; $R_c=10{,}000$ ohms; *G10* rectifiers; and Ford $2^1/_2$ watt servomotor drawing no. *979646*.

Fig. 10(A) is an oscillogram of the quiescent output current of this amplifier. Fig. 10(B) is an oscillogram of the output current of this amplifier with a 10-volt rms control signal. Fig. 10(C) is an oscillogram of the output current of this amplifier with a 10-volt rms control signal of the opposite phase. Fig. 11 is an oscillogram of the transient response of the amplifier to a suddenly applied 8-volt rms control signal. The upper trace is of the control signal which was suddenly and randomly applied.

Fig. 12(A) gives the 60-cycle component of the output voltage of the amplifier as a function of the control voltage when the amplifier is operating into a 200-ohm resistive load. The voltage gain in the

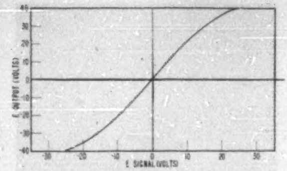

Fig. 12(A). Voltage gain versus input signal for laboratory circuit

range of 0- to 1-volt control signal is about 3; the voltage gain in the over-all range of the amplifier varies from about 3 to about 2. Measurements of the input impedance in the steady state give an input impedance of 20,000 ohms. Thus, the 0- to 1-volt control signal range has a power gain of about 900, and the over-all range of the amplifier from about 900 to about 400. This represents an optimum condition for the laboratory circuit described.

The conditions which bring about this optimum condition should be noted here. Starting with a given circuit with an equal number of control-winding and gating-winding turns, the voltage and power gains are very small, as expected. Decreasing the number of control-winding turns while maintaining the gating-winding turns constant will, at first, increase the voltage and power gains, also as expected. However, this procedure causes a decrease in the control-winding reset voltage and an increase in the control-winding magnetizing current. This, in turn, causes an increase in the control-circuit supply voltage and the various control-resistor and rectifier-voltage drops. Finally, the ratio of control-circuit supply voltage to control-winding voltage becomes so large that the small variations in control resistor and other voltages in the control-circuit become of the same order of magnitude as the control-winding voltage. This, therefore, puts a lower limit on the number of control-winding turns. Below this number, the optimum condition, the voltage and power gains decrease instead of increase.

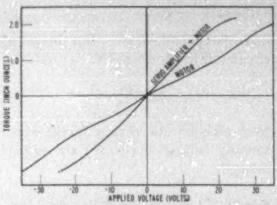

Fig. 12(B). Torque versus applied voltage for servomotor and for servo amplifier and motor

The impedance of the laboratory circuit tested was about 20,000 ohms in the steady state. However, in the dynamic state, the impedance seen by the control source is often that of the control resistor alone, thus necessitating its 10,000-ohm value. In addition, when large signals saturate the core, the control source will see only the control resistor.

Fig. 12(B) gives the locked-rotor torque of the servomotor as a function of the applied voltage. In one case, the applied voltage is applied directly to the control winding of the servomotor; in the other case, the applied voltage serves as the control signal of the amplifier whose output is applied to the control winding of the motor.

Conclusions

The new magnetic servo amplifier for 2-phase servomotor control has the major advantage of half-cycle response. It is simple and gives satisfactory operation for some applications with a single stage. The circuit is operable with either a-c or d-c control, and the control resistors can be varied at will through a wide range, enabling the circuit to be used with a wide variety of control sources. The circuit will or will not furnish a quiescent damping current as desired.

The circuit, however, has several disadvantages. The back electromotive force of the motor when running is detrimental to the operation of the amplifier throughout the entire cycle except when reversing the motor. In addition, the motor must carry the currents of both gating windings. All in all, the advantages outweigh the disadvantages, and it is believed that this circuit will find useful applications in the 2-phase servomotor control field.

A High-Accuracy Static Time Delay Device Utilizing Transistors

G. F. PITTMAN, JR.
ASSOCIATE MEMBER AIEE

THE fixed voltage-time integral value determined by the swing of the flux level of a rectangular hysteresis loop magnetic core from one saturation level to the other has been exploited in a variety of ways, e.g., in magnetic amplifiers, saturating transformers, etc. Nevertheless, extensive utilization of the integrating capabilities of cores has been limited by the functions which associated circuit components are capable of performing. Employing junction transistors as circuit components, however, opens new possibilities of using this characteristic of saturable cores to perform a variety of useful functions.

This paper describes circuitry employing junction transistors as nearly ideal, controlled switches in conjunction with rectangular hysteresis loop magnetic cores to perform pulse shaping and preset pulse-counting functions. By deriving pulses from a fixed frequency source, the circuitry may be designed to yield quite long time delays with extreme accuracy, because of the digital nature of operation employed. The circuitry and the manner in which transistors are used permits operation under conditions of relatively wide supply voltage variations and am-

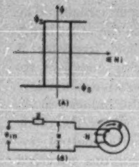

Fig. 1. A—Idealized rectangular hysteresis loop B—Simple saturable core circuit

bient temperatures extending to at least 80 degrees centigrade (C) without adversely affecting the timing accuracy.

Principles of Operation

Tape-wound toroidal cores of 50-50 nickel-iron alloy exhibit very nearly the idealized rectangular hysteresis loop shown in Fig. 1(A). Essential features of this magnetic characteristic are the sharp saturation at some definite core flux, ϕ_s, and the retention of the existing core flux level upon removal of all applied magnetomotive forces.

Let us suppose that such a core is provided with a winding and a voltage applied as in Fig. 1(B). The voltage $e = N(d\phi/dt)$ is the voltage "absorbed" by the core in changing its flux level in response to the applied voltage e_{in}. Change in core flux level can therefore be related to the volt-time integral of the voltage e

$$\Delta\phi = \frac{1}{N}\int_{\Delta t} edt$$

From this it is seen that, if core flux is changed from negative to positive saturation, a volt-time area must be supplied to the core equal to

$$\int edt = 2N\phi_s$$

If the voltage drop across the series impedance element Z of Fig. 1(B), which includes winding resistance as well as any other series impedances, is negligible compared to e_{in} and e, then

$$e_{in} = e$$

and

$$\int e_{in}dt = 2N\phi_s$$

Thus, if a low-resistance winding on the core is supplied with voltage from a low-impedance source, the core (assuming that it is driven from negative to positive saturation) integrates the input voltage with respect to time until a definite value of the integral is attained, at which time it saturates sharply. Because of the retentivity properties of rectangular loop cores, the input voltage need not be continuous but may be applied in the form of pulses; in this case the core retains the flux level at the end of one pulse until the next pulse is applied, and the integration process takes place as it would with a continuous voltage applied. Thus, for pulse input voltages

$$\int_{\Delta t_1} edt + \int_{\Delta t_2} edt + \int_{\Delta t_3} edt + \ldots + \int_{\Delta t_n} edt = 2N\phi_s$$

where $\int_{\Delta t_n} edt$ denotes the volt-time integral value of the nth pulse. If the input pulses are of fixed volt-time integral value; i.e., if

$$\int_{\Delta t_1} edt = \int_{\Delta t_2} edt = \int_{\Delta t_3} edt = \ldots = \int_{\Delta t_n} edt$$

then

$$n\int_{\Delta t_n} edt = 2N\phi_s$$

or

$$n = \frac{2N\phi_s}{\int_{\Delta t_n} edt}$$

so that a definite number of input pulses are required to saturate the core. It is this voltage integrating property of the rectangular loop saturable core, particularly with pulse inputs, which forms the basis of operation of the device to be described.

If a core is initially placed in the negative saturation state, and the saturation of the core in the positive direction is detected and an output signal immediately initiated, a variety of useful functions can be performed by virtue of the integrating property of the core. For instance, if the input voltage of Fig. 1(B) varies in a random manner with time, an output signal will be obtained when the time integral of the input voltage attains some fixed value as determined by the saturation flux of the core and the number of turns of the input winding. On the other hand, if e_{in} consists of a series of unidirectional pulses of equal volt-time area; then, as stated before, a fixed number of such pulses will be required to drive the core from negative to positive saturation, and an output signal will be obtained after application of a preset number of pulses. If such input pulses are supplied synchronously with a fixed frequency source; e.g., an a-c power source, a given number of pulses will represent a fixed time interval, and an output signal will be delivered after a preset time interval.

Since, in general, it is desirable to reset the core to negative saturation immediately after it has been driven to positive saturation, a convenient means of obtaining an output signal is provided, since the voltage induced in an output winding on the core during resetting serves ideally as an output pulse. Such a pulse has a fixed volt-time area determined by the core saturation flux and the number of turns of the output winding; thus, it is ideally suited to drive another core, operating in a similar manner, partially toward positive saturation. By such cascading, the range of integrating or counting can be greatly extended.

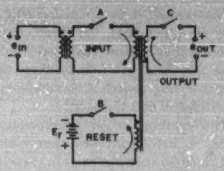

Fig. 2. Basic preset counter circuitry

Although the principle of operation of a magnetic core integrator, as just set forth, is quite elementary and straightforward, the circuitry required to reduce the principle to practice is quite specialized in its required functions.

Basic Circuitry

Basically three circuits are required. These are:

1. An input circuit and winding providing a means of applying input voltage pulses to the core.
2. A reset circuit and winding providing a means for resetting the core to negative saturation upon saturation in the positive direction.
3. An output circuit and winding providing a means of applying the induced voltage during resetting to a load or succeeding stage.

These circuits are shown schematically in Fig. 2, each incorporating a switch which it is assumed may be opened and closed at appropriate times.

During an input voltage pulse, it is desired that the entire input voltage be translated into core flux change. This dictates that the input circuit possesses low series impedance other than the inductive impedance of the core and that current flow in the input circuit be kept to a minimum. The latter condition implies that there be no loading on the core due to other circuits' linking it. Therefore, during input pulsing, it is required that switch A be closed and switches B and C be open.

During resetting it is desired that the resetting battery voltage be applied to the resetting winding and that the voltage induced in the output winding be transmitted to the output terminals. Since the input circuit has been specified to be of very low impedance, it is necessary that switch A be opened during resetting in order that the input circuit shall not act as a short-circuited winding linking the core. It follows then that, during resetting, switch A should be open and switches B and C closed.

During intervals of zero input voltage, switches A and C may be either open or closed since no voltages exist in these circuits during such intervals. Switch B, however, must be open since the resetting battery would otherwise be applied to the resetting winding causing premature resetting to take place.

It should be noted that switch C is required to permit all current flow in one direction and block all current flow in the opposite direction; therefore, a simple diode will serve adequately the purpose of this switch. Switches A and B, however, are required both to block and to permit current flow in the same direction, depending upon the circuit operation being performed at a given time. Simple diode elements will therefore not perform the functions required of switches A and B.

A Practical Pulse-Integrating Circuit

In the circuit shown in Fig. 3, transistors A and B perform the functions of switches A and B respectively of Fig. 2, while the diode in the output circuit performs the function of switch C. In this circuit, input voltage pulses are supplied through a transformer having two secondary windings in order to both apply voltage to the input circuit and also to apply, simultaneously, the appropriate driving voltage to the base of transistor A.

It has been shown[1] that a junction transistor can function as a nearly ideal switch between its emitter and collector electrodes if appropriate driving voltages and currents are applied to the base electrode. The pertinent conditions may be summarized as follows (for *P-N-P* transistors).

1. With the base positive with respect to both the emitter and the collector, the transistor acts as an open switch, permitting only a very small leakage current to flow in the emitter-collector circuit.
2. With the base negative with respect to either the emitter or the collector, the transistor acts as a closed switch, offering very low resistance to current flow in the emitter-collector circuit.

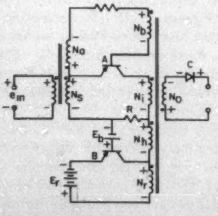

Fig. 3. Preset counter circuit during an input pulse

During application of an input pulse the polarities of voltages existing on the various windings of the transformer and saturable core are as shown in Fig. 3. The voltage induced in winding N_a is of such polarity as to drive the base of transistor A negative with respect to its emitter and thus permit current flow from emitter to collector. The input pulse voltage induced in N_s is thus applied directly to winding N_i of the saturable core, the value of resistor R being such that the voltage drop of the core magnetizing current is negligible. As a result of the voltage applied to N_i, voltages are induced in windings N_b and N_h as shown. The voltage induced in N_b adds to the existing voltage applied to the base of transistor A to render it conducting, while the voltage induced in N_h adds to the bias voltage E_b applied to the base of transistor B to hold it blocking. The output diode, meanwhile, blocks the voltage induced in N_0 from the output terminals. Thus the conditions specified for the input pulsing interval are fulfilled, i.e., switch A is closed while switches B and C are open.

During intervals between input pulses, no voltages exist on any of the windings of the saturable core. During this time the bias battery in the base circuit of transistor B holds it blocking, thus preventing the application of the resetting voltage E_r to winding N_r. It may be noted that any negative input pulses will be blocked from the input winding by transistor A since the voltage induced in N_a will be of a polarity to block A rather than rendering it conducting as is the case with a positive input pulse.

Upon saturation of the core during some input pulse, the induced voltages in the saturable core windings disappear and the pulse voltage appears across resistor R. This voltage, which also appears in the base circuit of transistor B, overcomes the bias battery voltage, placing a negative potential on the base of B and causing it to cease blocking. The resetting voltage E_r is thus applied to N_r and resetting of the core is initiated. During resetting the polarities of voltages existing in the circuit are as shown in Fig. 4.

The voltage induced in N_b is of such a polarity as to place a positive potential on the base of transistor A, thus blocking current flow in the input circuit. The voltage induced in N_h, on the other hand, is of the polarity to hold transistor B conducting, thus insuring complete resetting of the core to negative saturation. The output voltage pulse induced in N_0 during resetting is passed by the diode and a signal appears at the output terminals. Thus, all conditions specified for the resetting interval are met, i.e., switch A is open while switches B and C are closed.

It may be noted in Figs. 3 and 4 that the resetting transistor is used in an inverted connection, i.e., when acting as an open switch the collector is positive with respect to the emitter. This connection is used here in preference to the normal one to minimize leakage current during blocking which might otherwise cause partial resetting in the intervals between input pulses, and result in inaccurate counting.

A Fixed Time Delay Device

As pointed out previously, the pulse-integrating circuit functions as a preset counter if supplied with input pulses of constant volt-time area, and a preset time delay if these pulses are synchronous with a fixed frequency source. A saturating transformer driven from a fixed frequency source would provide such pulses; however, to provide more nearly ideal switching of the transistors, a rectangular input pulse is desirable.

The pulse-shaping circuit shown in Fig. 5 produces, in response to an input pulse, a rectangular output pulse of fixed volt-time area. Suppose that initially the saturable core has been reset to negative saturation under the influence of E_p acting on winding N_r through resistor R. The transistor is held in the blocking state by the bias voltage E_b applied to its base. An input pulse of the polarity shown overcomes the bias voltage rendering the transistor conductive and applying E_p directly to winding N_p. Since the transistor emitter-collector circuit represents a much lower impedance than R

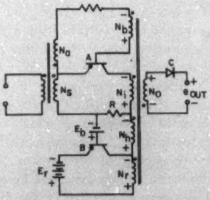

Fig. 4. Preset counter circuit during resetting

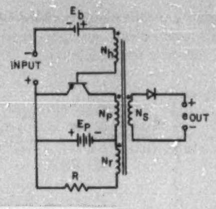

Fig. 5 (left). Pulse shaper circuit

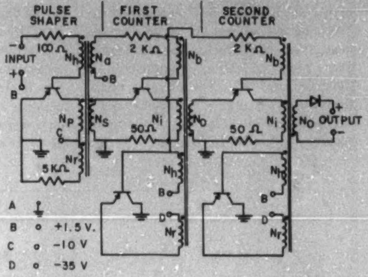

Fig. 6 (right). Pulse shaper and 2-stage preset counter circuit

(on a common turns base), the core is driven toward positive saturation, the voltage induced in winding N_h acting to hold the transistor conducting until the core saturates. The rectangular voltage pulse induced in the output winding N_s during this time has a fixed volt-time area determined by the saturation flux of the core and the number of output winding turns. Upon saturation of the core the induced voltages disappear and again the transistor blocks. The core is then reset through the N_r circuit in preparation for the next input pulse, the diode in the output circuit blocking the induced voltage during resetting from the output terminals. Thus, in response to a rather arbitrary input pulse, the pulse-shaping circuit delivers a unidirectional rectangular pulse of fixed volt-time area.

In combining a pulse-shaping circuit and a number of cascaded counter stages, output windings of the preceding stage serve as the transformer secondary windings shown as the input in Figs. 4 and 5. Furthermore, the output diode is necessary only in the last stage since the input transistor of the succeeding stage serves this purpose as well as its other switching functions. In such a series of cascaded staegs, each is isolated, by virtue of the solely magnetic coupling, from the others. Therefore, regardless of the number of stages, only one common d-c power supply is required.

The use of a saturable-core pulse shaper and the means employed to derive output pulses from the counter stages provide an important stability feature when a pulse shaper and several stages are operated in cascade, e.g., in order to obtain long time delays. The saturation flux of saturable magnetic cores varies somewhat with temperature; this variation becomes quite appreciable when wide ambient temperature variations, e.g., −65 to +70 C are considered. Thus, if input pulses of truly constant volt-time area are applied to a counter stage, the number of pulses required to drive the core from negative to positive saturation will vary with ambient temperature, introducing inaccuracy in the time delay. However, by using the swing of a core from saturation to saturation to determine the volt-time area input to each stage, as is done in the circuitry described, no inaccuracy will be introduced if all cores (pulse shaper and counter stages) vary in a like manner with temperature. Since, in general, all cores will be of the same material, this will be quite nearly the case. Furthermore, since transistors are used in such a manner that they exhibit quite negligible voltage drops when conducting and very small leakage currents when blocking, wide variations in transistor characteristics, both between units and with temperature, may be tolerated without affecting the operation of the circuit. The net result of these considerations is that accurate and reliable operation, unaffected by wide ambient temperature variation, is obtained.

Experimentation

Time delay units have been built up consisting of a pulse shaper and two cascaded counter stages as shown for example in Fig. 6. In this unit a somewhat different method of detecting saturation of the counter core is employed than shown in Figs. 3 and 4. Instead of using the voltage developed across a series resistor upon saturation of the core to trigger the resetting transistor, the voltage induced in the resetting transistor holding winding (N_h of Figs. 3 and 4) as the core flux drops from its maximum saturated value back to the residual value at the end of the input pulse is employed. Furthermore, the function of winding N_a of Figs. 3 and 4 is performed in the circuit of Fig. 6 by other windings in addition to their other functions. On the pulse-shaper core the series combination of windings N_s and N_a is used, while on the first counter core windings N_0 and N_h are used. This is possible since the method of saturation detection employed here eliminates the necessity for the resistor common to the input circuit and the resetting transistor base circuit of a counter stage, also enabling the common bias voltage to be used as a blocking bias in the base circuit of the counter stage input transistor of Fig. 6. This bias voltage ensures more complete blocking of the input transistor, especially under conditions of high ambient temperature. Despite these changes, however, the operation of the circuit is essentially the same as that described in the preceding section.

The unit shown in Fig. 6 is designed to require 10 input pulses to saturate each stage; thus 100 input pulses are required to saturate the last stage and yield an output pulse. The saturable cores used in the circuit are all wound toroids of 2-mil Hipernik V material. All transistors are Westinghouse *P-N-P* junction type *2N56*.

Using input pulses derived from the 60-cycle power line, the unit was checked for operation over an ambient temperature range of −65 to +80 C. In all cases 100 input pulses were required to obtain an output pulse from the second stage. Because of the digital nature of the device, it is expected that such absolute accuracy would be carried through to units of many more stages and, consequently, much longer time delays.

To check the retention of information (i.e., existing counter core flux level) over long periods of time, input pulses were turned off after less than 100 were supplied, and then turned on again after intervals up to 8 hours. It was found that, despite the elapsed time, the proper total number of input pulses produced an output signal. These results indicate that, by cascading stages, time delays in excess of 8 hours should be obtainable with an accuracy of considerably less than 1 half cycle of the input pulse frequency.

Conclusion

Circuitry employing junction transistors and rectangular hysteresis loop magnetic cores has been described which enables effective utilization of the voltage integrating capabilities of the core to perform preset counting operations. An example has been given of an application of such circuitry in a fixed time delay device to provide very long delays to an accuracy of a small fraction of the period of the fixed frequency source from which it is driven.

The components and circuitry which are employed are such that reliable operation is obtained over wide ambient temperature ranges and with wide tolerances on power supply voltage variations. The device is expected to display the excellent reliability and life which are characteristic of its components, junction transistors and saturable magnetic cores.

A New Audio Telegraph Carrier Terminal

C. A. HIGGINS
NONMEMBER AIEE

E. A. GILBERT
ASSOCIATE MEMBER AIEE

A NEW telegraph carrier terminal has been developed to meet the ever-increasing demand for telegraph communication facilities. The terminal is designed to meet the frequency spectrum requirements for 12-channel telegraph systems.[1] These standards were set up to allow the telegraph communication systems of the U. S. Army, Navy, and Air Force and many existing commercial systems to be integrated for joint use in the interest of national defense.

Application

Normal center frequencies of the telegraph channels are at 425, 595, 765, 935, 1,105, 1,275, 1,445, 1,615, 1,955, 2,380, 2,805, and 3,230. The first eight channels are 170 cycles wide with the space frequency 42.5 cycles per second (cps) below center-band frequency and the mark frequency 42.5 cps above center-band frequency. The last four channels are 425 cps wide with the space frequency 85 cps below center-band frequency and the mark signal 85 cps above center-band frequency. The tolerance allowed on the mark and space frequencies as generated is ±3 cps. The narrow-band channels are capable of transmitting telegraph messages up to 100 words per minute. Broad-band channels transmit high-speed messages up to a 250-words-per-minute rate or carry four time-division multiplex telegraph channels at 60 words per minute.

The equipment described in this paper is used for fixed-plant installations under conditions of continuous operation over extended periods of time. Reliability, long life, simplicity of design, and ease of maintenance are the guiding considerations for equipment of this type. Front panel test jacks are provided for system trouble-shooting and initial installation adjustments. Both land lines and radio links are used for connecting the transmitting and receiving sections. For long-distance radio links, the equipment may be switched into a frequency diversity system and, with slight modification, can be used for space diversity operation. Fig. 1 shows the complete 12-channel terminal with the transmitting units mounted in the cabinet at the right and the receiving units mounted in the cabinet at the left. The individual chassis are $5\frac{1}{4}$ inches high and may be withdrawn from the cabinet and turned up for maintenance, as shown in Fig. 2.

Because this equipment has a wide field of application, many options are required in electric connections and circuitry. Plug-in frequency-determining components are used to permit the exchange of basic chassis units for maintenance purposes and to permit future conversion of the equipment to a 16-channel system or other systems, as may be desired. Fig. 3 shows a complete filter set for one telegraph channel.

Group modulator or frequency converter units are provided for converting the frequencies of the narrow-band channels into the frequency spectrum of 1,742.5 to 3,017.5 cps for transmission with the normal narrow-band channels to make a 16-channel system. The 1,742.5- to 3,017.5-frequency spectrum is modulated again at the receiving end and converted to the normal channel frequencies.

Systems

A block diagram of a typical terminal system with 12 telegraph channels is shown in Fig. 4. Twelve sending teletype printers and twelve receiving teletype printers are required. The communication link may be either a land line or a radio circuit. In the output of each transmitter unit is a 20-decibel (db) band-pass filter that can be operated in parallel with others of the same type. These filters attenuate frequencies 20 db or more in the adjacent channels. Outside the passband the shunt reactance is high. Only the amplifiers of the transmitter and receiver frequency converters are used in this connection. The input to each receiver unit is a 40-db band-pass filter that is operated in parallel with the other 11. An application of the frequency converters in a 16-channel system is shown in Fig. 5. The channels 9 through 16 are modulated in the transmitter frequency converter against a precise 3,400-cps crystal-controlled standard frequency and converted to the 1,742.5-cps-to-3,017.5-cps frequency range. After transmission, these frequencies are again modulated against a 3,400-cps standard frequency and are returned to their normal frequencies.

Transmitter Unit

The transmitter group contains 12 telegraph transmitter units. These units convert the d-c telegraph pulses in the loop circuit to frequency shift "mark" and "space" audio signals for each channel. Each transmitter consists of a 15-kc loop oscillator, a d-c amplifier with tele-

graph bias controls, a plug-in frequency-shift tone oscillator, an output amplifier, a plug-in 20-db band-pass filter, and power supplies. The arrangement of these circuits is shown in the block diagram of Fig. 6. The 15-kc loop oscillator isolates the d-c loop circuits from the transmitter chassis which is at ground potential. The 15-kc signal is rectified and applied to a d-c amplifier. Telegraph bias correction controls are designed into the d-c amplifier. The tone oscillator is a resistance stabilized Hartley circuit, the frequency of which is shifted electronically by adding capacitance to the tuned circuit with a diode switch. Two power supplies are included in the unit; a 120-volt d-c supply for the telegraph loop circuit, and a 216-volt d-c supply for the amplifiers and oscillators. The loop-circuit current can be supplied from either the internal power supply or external battery, and is selected by a switch in the equipment. The unit operates from a single-phase power source of 115/230 volts, 50/60 cycles. Controls are included for loop-current adjustment and for signal output level. Mark and space output levels are within 1 db and can be adjusted over a range from −35 to +6 db referred to 1 milliwatt.

Receiver Unit

As shown in Fig. 4, the receiver group contains 12 telegraph carrier receiver units. These units convert the frequency shift audio telegraph signals of each channel to d-c pulses for operation of a telegraph printer or other telegraph and equipment. As shown in Fig. 6, each telegraph carrier unit consists of a plug-in 40-db band-pass filter, a limiting amplifier, a plug-in discriminator, a d-c amplifier, and a polar or neutral output circuit. A conventional power supply is included to operate the vacuum-tube circuits as well as to supply the loop current. By throwing a switch, an external battery may be used for the loop-circuit current. Because of the signal-fading conditions normally encountered on radio circuits, the limiting amplifier is designed to operate between +6 and −40 db referred to 1 milliwatt.

Frequency Diversity

Frequency diversity connections are made by switches on each chassis. Fig. 7 shows a block diagram of two receiver units in frequency diversity. The channel center-band frequencies of diversity pairs are spaced apart by 500 or more cycles for two reasons: a selective signal fade on a radio circuit will at times attenuate one of the carrier channels 40 db or more and not affect another signal spaced 500 cps away at the same instant; and the passbands of the two discriminators must not overlap or telegraph bias

distortion is introduced when one signal fades out. In the frequency diversity system used, one telegraph printer keys two telegraph carrier transmitter units. The block diagram of Fig. 7 shows the arrangement of two typical units with center-band frequencies at 425 and 1,105 cps. The audio output of both telegraph carrier transmitters is transmitted over a radio link to the receiving site. Audio signals from the output of the radio receiver are selected from the common bus with band-pass filters. The signals are added with equal value resistors *R1* and *R2*, and applied to the first grid of a common limiting amplifier. When one signal frequency is twice the amplitude of the other, the output of the limiting amplifier contains the frequencies of the greater channel. The discriminator of the channel with the greater signal level then controls the d-c amplifier and output keyer circuit. When both signal levels at the input amplifier are equal, the telegraph signal level at the input to the d-c amplifier is about ±5 per cent greater than when the signals are unequal. Limiting action of the d-c amplifier prevents this change of telegraph signal level from creating telegraph distortion in the output keyer circuit. An approximation of the effectiveness of this frequency diversity system may be obtained by assuming that each diversity signal developed in a single antenna by sky wave signals follows the Rayleigh distribution and fade independently.[2,3]

Accordingly, the fraction of unusable time that both signals may be faded below the least usable signal simultaneously is

$$t/T_0=[1-\epsilon^{-0.693(E_L/E_M)^2}]^2$$

where E_L is the least usable signal voltage and E_M is the median signal amplitude which is the amplitude exceeded one-half of the time. For small values of E_L/E_M, this equation simplifies to fraction of unusable time $t/T_0 \approx (0.693)^2 (E_L/E_M)^4$. For a typical system with equal channel sensitivity, the mean signal is about −10 db referred to 1 milliwatt and the least usable signal is −40 db referred to 1 milliwatt when the peak noise is −40 db referred to 1 milliwatt or below. This gives a value for E_L/E_M of 30 db or a voltage ratio of 0.032. On the basis that a 10-millisecond fade may cause an error in the operation of the telegraph printer, one error every 5 hours is calculated as probable. The actual errors experienced are usually greater than estimated because the fading of each signal is not entirely independent of the fading of the other and, also, the least usable signal varies because of changing noise levels.

Conclusion

The equipment described in this paper has been subjected to standard military climatic tests and has been found to operate satisfactorily in the ambient temperature range of 0 to 50 degrees centigrade at humidities up to 95 per cent. Performance has met the design objective. Production quantities of the terminals have been manufactured and delivered to the Armed Services. Many of these equipments are now in continuous daily use.

An Analysis of Optimum Core Configuration for Magnetic Amplifiers Using a Simplified Approach

B. D. BEDFORD
FELLOW AIEE

C. H. WILLIS
FELLOW AIEE

G. C. DODSON
ASSOCIATE MEMBER AIEE

When the engineer designs a device or a component he is always interested in achieving an optimum of one characteristic with respect to another. He might, e.g., wish to build a cylindrical capacitor. His optimization problem might be to find proportions of the cylinder which will yield the greatest capacitance for a given weight or cost of materials, all other design considerations being held fixed.

Typically, the designer is unable to invest the time and effort necessary for the solution of an optimization problem. More often than not, the explicit mathematical solution for even common, practical problems is prohibitively complex and the trial and error process is interminably laborious. In the latter process, only the highly skilled and experienced engineer can make a wise choice in successive trial proportions.

The object of this paper is twofold: first, to show the use of a little-known criterion with common differential principles in what the authors have found to be a simplified optimization process; secondly, to present the results achieved with this approach in analyzing optimum reactor configurations for magnetic amplifiers. The approach or method is explained in detail so that it might be adapted by others to their own problems. A practical example, one of the difficult cases in the magnetic amplifier analysis, is detailed in Appendix IV. A mathematical proof of the criterion is presented in Appendix I.

It is the little-known criterion, based on linear dimension relationships, that is the crux of simplifying the optimization process. The process or method is referred to here as the "Application of Infinitesimal Per-Unit Increments." Its simplicity comes not only from reduced algebraic operation but also in keeping the user in close touch with the elements of the design rather than isolated from them by mathematical manipulations.

designed component in an effort to improve it in some way. In the use of infinitesimal per-unit increments, the same general procedure applies but with greater resolution of purpose and less practical expense. There are five major steps involved:

1. In the first step it is necessary to identify the two characteristics which will be used to determine the optimum, i.e., maximum volume for a given weight of material, best gain for a given cost, etc. These characteristics must be expressed in terms of the physical dimensions and material design parameters of the device. The expressions obtained will be homogeneous polynomials, i.e., each term of the polynomial is the product of the same number of dimensions—homogeneous in degree. For a cylinder where the maximum volume for minimum surface is desired, volume V and surface S are expressed as

$$V=\frac{\pi D^2H}{4} \qquad (1)$$

$$S=2\left(\frac{\pi D^2}{4}\right)+\pi DH$$

These are the characteristics for optimization.

2. Secondly, it is necessary to determine the power of linear dimension to which the two optimizing characteristics are responsive. In the case of surface area, as mentioned in the foregoing, it is responsive to the second power of linear dimension—each term is proportional to the product of two dimensions or

$$S=\frac{\pi D^2}{2}+\pi DH \propto l^2 \qquad (2)$$

$$V=\frac{\pi D^2H}{4} \propto D^2H \propto l^3 \qquad (3)$$

In general terms, the design characteristics will be homogeneous polynomials of the type

$$P=\sum_{i=1}^{n} A_i w^{p_i} x^{q_i} y^{r_i} \qquad (4)$$

where

$$p_i+q_i+r_i=K \text{ (degree of each term)} \qquad (5)$$

3. In the third step, a shape for the device is assumed. For this shape, infinitesimal per-unit increments are applied to individual dimensions and the per-unit incremental changes in the optimizing characteristics are noted. This is done for each dimension in turn. This step is a simple algebraic operation the simplicity of which comes from the principles of differentials. Take any term T of the polynomial P such as

$$T=A_1 w^{p_1} x^{q_1} y^{r_1} \qquad (6)$$

Apply increments to each variable w, x, and y and note the effect on the dependent variable T

$$\Delta T_{\underline{w}}=\frac{\partial T}{\partial w}dw=\frac{\partial T}{\partial w}w\frac{dw}{w}$$

$$=A_1p_1w^{(p_1-1)}x^{q_1}y^{r_1}w\frac{dw}{w}=p_1T\frac{dw}{w} \qquad (7)$$

The actual value of $(dw)/w$ being quantity $a\mathfrak{u}$

$$\Delta T_{\underline{w}}=p_1Ta\mathfrak{u} \qquad (8)$$

Similarly

$$\Delta T_{\underline{x}}=q_1Tb\mathfrak{u} \qquad (9)$$

$$\Delta T_{\underline{y}}=r_1Tc\mathfrak{u} \qquad (10)$$

hence

$$\frac{\Delta T}{T}=(p_1a+q_1b+r_1c)\mathfrak{u} \qquad (11)$$

If all dimensions are increased the same number of finite per-unit increments

$$a=b=c=1 \qquad (12)$$

and

$$\frac{\Delta T}{T}=(p_1+q_1+r_1)\mathfrak{u}=K\mathfrak{u} \qquad (13)$$

Thus, the simplicity of using infinitesimal per-unit increments becomes apparent. The per-unit increment in a dependent variable $A=BCD$ is the sum, not the complete complex product, of the individual per-unit increments. Writing the general total differential statement in a form particularly useful for this method

$$\frac{\Delta U}{U}=\frac{w}{U}\frac{\partial U}{\partial w}\mathfrak{u}_w+\frac{y}{U}\frac{\partial U}{\partial y}\mathfrak{u}_y+\frac{x}{U}\frac{\partial U}{\partial x}\mathfrak{u}_q\ldots \qquad (14)$$

At this point, an evaluation of the assumed shape is made on the basis of the following criterion. "If the device has optimum shape, the ratio between the resulting per-unit increments in optimizing characteristics is equal to the ratio between exponents or powers of linear dimension for these characteristics." See Appendix I for proof. For example, if volume responsive to the third power of linear dimension were being optimized against surface area responsive to the second power the application of increments to any one dimension should result in a 3-to-2 ratio of volume increments to surface increments for optimum shape, i.e., if shape is optimum and $(\Delta H)/H=m\mathfrak{u}$, the ratio which must hold is

$$\frac{\dfrac{\Delta V}{V_{\underline{H}}}}{\dfrac{\Delta S}{S_{\underline{H}}}}=\frac{3}{2} \qquad (15)$$

For $(\Delta D)/D=m\mathfrak{u}$

$$\frac{\dfrac{\Delta V}{V_{\underline{D}}}}{\dfrac{\Delta S}{S_{\underline{D}}}}=\frac{3}{2} \qquad (16)$$

If any one dimension is small in comparison to the other dimensions for optimum performance, applying increments to it will yield a greater than 3-to-2 ratio between volume and surface increments. The reverse is similarly true.

4. The fourth step is obvious. After evaluating the assumed shape, it can now be judiciously reproportioned toward the optimum. The amount of correction necessary is indicated by the extent to which the incremental characteristic ratios correspond to the desired linear dimension ratios. The increments are again applied and the second trial shape is evaluated.

5. In the fifth step, the process of correcting proportions and recalculation of rates of characteristic change is continued until the optimum shape is achieved. Few trial shapes are required if the work is pursued in a planned, orderly fashion. On some of the simpler problems, the application of infinitesimal per-unit increments leads directly to simple simultaneous algebraic equations which can be solved explicitly for the optimum shape. The real value of the method is not for solving this simple type of problem but rather for the more complex problem leading to simultaneous equations which can be solved only with great difficulty.

An Academic Illustrative Problem

The simple problem of proportioning a right circular cylinder, both ends closed, for the maximum volume and minimum surface will effectively illustrate the method. This is the practical problem in making economical tin cans from the material approach alone. It is a problem which is very easily solved by the mathematical method. From the mathematical solution the optimum proportions are realized when the diameter is equal to the height. Apply the method of infinitesimal per-unit increments as follows:

1. The expressions for volume and surface are

$$V=\frac{\pi D^2H}{4} \qquad (17)$$

$$S=\frac{\pi D^2}{2}+\pi DH \qquad (18)$$

2. Volume is responsive to the third

power of linear dimension and surface is responsive to the second power of linear dimension

$$V \propto l^3 \tag{19}$$

$$S \propto l^2 \tag{20}$$

3. Assume that the height is three-fourths of the diameter $H/D=3/4$. Apply an increase of three (or any number) infinitesimal per-unit increments to H and evaluate the resulting increments on V and S. They should have the ratio of 3 to 2. Regarding V, if $(\Delta H)/H=3\mathbf{u}$, then

$$\frac{\Delta V}{V_{\underline{H}}}=\frac{H}{V}\frac{\partial V}{\partial H}\frac{\Delta H}{H}=3\mathbf{u} \tag{21}$$

Regarding S, if $(\Delta H)/H=3\mathbf{u}$, then

$$\frac{\Delta S}{S_{\underline{H}}}=\frac{H}{S}\frac{\partial S}{\partial H}\frac{\Delta H}{H}=1.8\mathbf{u} \tag{22}$$

For this step it is convenient to evaluate $(\Delta V)/V_{\underline{H}}$ and $(\Delta S)/S_{\underline{H}}$ by simple inspection. It is obvious that V responds directly to the percentage change in H. S responds to the $(DH)/(D^2/2+DH)$ fraction of the percentage change of H evaluated on the basis of $H=3$, $D=4$, i.e.

$$\frac{\Delta S}{S}=\frac{12}{16/2+12}3\mathbf{u}=1.8\mathbf{u}$$

Evaluating

$$\frac{\dfrac{\Delta V}{V_{\underline{H}}}}{\dfrac{\Delta S}{S_{\underline{H}}}}=\frac{3\mathbf{u}}{1.8\mathbf{u}} \tag{23}$$

which is greater than the desired ratio of 3 to 2. Therefore H is too small with respect to D.

4. Since H is small with respect to D, increase H so that $H=D$. Regarding V, if $(\Delta H)/H=3\mathbf{u}$, then

$$\frac{\Delta V}{V_{\underline{H}}}=3\mathbf{u} \tag{24}$$

Regarding S, if $(\Delta H)/H=3\mathbf{u}$, then

$$\frac{\Delta S}{S_{\underline{H}}}=\frac{1}{1/2+1}3\mathbf{u}=2\mathbf{u} \tag{25}$$

Evaluating

$$\frac{\dfrac{\Delta V}{V_{\underline{H}}}}{\dfrac{\Delta S}{S_{\underline{H}}}}=\frac{3\mathbf{u}}{2\mathbf{u}} \tag{26}$$

as desired. Therefore the optimum shape of the right circular cylinder is realized for $H=D$.

Discussion of the Method

Any device can be described by a number of physical dimensions and other coefficients. A number of ratios, one less than the number of physical dimensions, completely establishes the configuration or shape of the device. If all of the dimensions of a device are increased by the same infinitesimal per-unit increment, the ratio between resulting increments in the characteristics for optimization will be equal to the ratio of the exponents of generalized linear dimension to which the characteristics are responsive. This is true for any shape. For the optimum shape, however, each individual dimension has the same degree of effect on characteristics as the others. Applying increments to one dimension alone under these circumstances approaches the same effectiveness as increasing all dimensions simultaneously and, hence, will also result in characteristic increments in proportion to the ratio of dimension exponents. See Appendix I for proof.

A significant factor in seeking optimums is seen by referring back to the cylinder problem. "Optimization is not achieved between two characteristics by holding one dimension constant and varying the other until the ratio of characteristics goes through a maximum." A maximum does not occur. V/S does not go through a maximum as H is increased for a fixed value of D. The optimum is truly defined only as the maximum value of volume V for a fixed value of surface S (or minimum value of S for fixed V). This is the condition sought out by the mathematical solution and the solution by infinitesimal per-unit increments.

The method is applicable to optimum determination where one ratio is restricted as well as the completely free case. This is of practical importance where it might be found that a completely free optimum yields ungainly proportions. By restricting one ratio to a fixed value, the optimum can be recalculated yielding a completely new optimum configuration.

It should be emphasized that some problems can very easily be solved by the generally useful mathematical method. It can consist of first taking the differential of the polynomials describing the two optimizing characteristics. These are set equal to zero for the condition of maximum-minimum and the ratios of coefficients of like differentials in the two expressions are equated. This yields simultaneous algebraic equations the solution of which represents optimum shape. This straightforward mathematical approach was used in solving the resistance-limited punched core reactors but became extremely difficult for the thermally limited reactor and the toroid cases.

The method described is a tool to use in conjunction with intimate knowledge of a component design. The designer will know whether his problem is yielding a maximum or a minimum from the nature of the optimizing characteristics. He will rarely find a practical problem where he has several maxima and even less rarely find a case where he can ambiguously solve for a minimum where a maximum is sought. Conventional mathematical means must otherwise be employed to answer this kind of question if the answers are not already evident in the character of the design.

Considerations for Optimizing Magnetic-Amplifier Reactors

Magnetic-amplifier reactors might be built as toroids using wound cores, or by conventional transformer techniques using stacked, punched cores. In small reactors, performance, gain, and time constant should be the criterion on which optimization is based. Economy of materials is comparatively unimportant since most of the cost for the small reactor is in assembly. Similarly, power efficiency is unimportant in considering operation costs. The most important item then is figure of merit, expressed as d-c power gain per second of control-circuit time constant. Gain should be optimized for a given time constant. This is true for both punched and wound cores.

For very large reactors (roughly 10 kw and above), economy of materials and power efficiency become important and performance assumes decreasing importance. It is desirable then to realize the greatest power output possible for a given cost or quantity of materials.

The foregoing represents one set of considerations for optimization. Particular applications might dictate optimizing characteristics other than these and will accordingly influence the assumptions, complexity of the analysis, and the resulting optimum shapes.

THE RESISTANCE-LIMITED OR SMALL REACTOR

Efficiency being unimportant in small reactors, it is possible to match the load resistance to the reactor winding resistance for maximum power transfer to the load. Under these circumstances, current density in the power winding is analytically related to the rating or size of the reactor such that, as rating increases, current density increases. This is developed in Appendix II along with the optimizing parameters. The maximum rating or size for which this relationship is valid occurs when current density is sufficiently high to tax, to the fullest, the power-dissipation ability of the reactor's surface. This defines the case for the resistance-limited reactor. From the analysis, the resistance-limited case is confined to reactors rated roughly 5 volt-amperes or smaller. At higher ratings, the reactor is governed by thermal limitations and load resistance must be larger than a-c winding resistance to keep current density within thermal allowances.

After-saturation characteristics of the reactor are negligible for this size of reactor, as experience shows that the maximum *H* or magnetizing force does not reach 1,000 oersteds. This is the point at which the air core flux of the winding introduces a noticeable addition to the relatively flat, intrinsic saturation flux density of the core material. The squareness of the hysteresis loop for the material affects the abruptness of firing but does not affect the substantially resistive character of load circuit impedance while load current flows.

The Thermally Limited or Large Reactor

Large reactors, ratings beyond the maximum of 5 volt-amperes for the resistance-limited case, are thermally limited. Current density in the a-c windings is analytically related to the amount of heat-dissipating surface the reactor possesses. This is developed in Appendix III. As the reactor is made larger, load resistance must be made a greater and greater proportion of the a-c circuit resistance to keep current density within thermal limitations. This improves reactor efficiency toward a limit of 100 per cent.

The analysis, to yield results, must be made on the basis of a negligible portion of input power being lost in the reactor, the ideal situation for the large reactor. Reactor current rating, on the other hand, is directly related to the reactor power loss. When a per-cent power loss for the reactor is chosen, consistent with what can be looked upon as practical negligible loss of input power, the reactor rating is at once defined analytically. 2.5 Per cent of input power was chosen as a reasonable figure and this yielded an output rating of about 10 kw. Since efficiency increases with rating, this means that the thermally limited analysis applied to ratings above 10 kw.

Optimizing Objective

With optimum shapes realizable for small reactors below 5 volt-amperes and large reactors above 10 kw, the undefined region in between represents an area of compromise between two kinds of optima. A semilogarithmic compromise between the shape ratios appears appropriate as a general guide for punched core reactors. As a matter of fact, these two power levels are figures safely in the power range of the aforementioned two general design cases. The analysis of a specific reactor arrangement will yield limiting power level between these. The analysis can be used to guide resistance-limited designs much larger than 5 volt-amperes and thermally limited designs much smaller than 10 kw, even to the point where these two limits overlap. Thus, the designer can weight his design in the 5-volt-amperes to 10-kw range in favor of the preferred of the two merit cases described.

Assumptions for the Analysis

Many factors influence the design of a reactor. This method permits the simultaneous consideration of more of these factors than is commonly convenient for the designer. The analysis covers the important factors. Assumptions are made regarding those which have little effect on optimization results. Considerations of these would yield very little improvement in the optimum but would add much to problem complexity. This does not imply that they are neglected in application considerations. It is assumed that:

1. Core losses can be neglected. For the 60-cycle resistance-limited reactor, core losses are such a small proportion of output power and reactor copper loss that they have only a small effect on shape. The thermally limited design is based on dissipating the greatest possible reactor losses without exceeding permissible reactor temperatures—a condition fulfilled in 60-cycle reactors when they are phased full on. Here, copper losses predominate and iron losses are very small since the core is fully or almost fully saturated during all parts of the cycle.

2. The cross section of the magnetic path is uniform and continuous. As long as the air gap of stacked cores is a small, fixed proportion of the magnetic path, the analysis is unaffected.

3. The rectifiers are ideal rectifiers. Silicon and germanium rectifiers with extremely high back resistance approximate this condition in reverse characteristics. This is important to the resistance-limited case where reverse current effects the gain portion of the optimizing characteristics as a function of shape. With selenium rectifiers, the optimum accuracy is not as good. On the other hand, in the thermally limited reactor analysis, rectifier leakage has negligible effect on reactor heating and maximum power output and, thus, has no practical effect on reactor shape. Rectifier forward voltage drop is a sufficiently small part of load circuit voltage so that it has little effect on shape determination. Furthermore, if the forward voltage drop were always a fixed proportion of the load circuit voltage, the analysis would be unaffected.

4. The after-saturation reactance of the reactor power winding can be neglected. It is responsive to shape changes in only a small way. The small values of *H* at which resistance-limited reactors operate make air core flux a much less significant factor than it is in even the thermally limited reactor. Finally, if after-saturation reactance as a significant quantity were always a fixed proportion of load circuit impedance, the analysis would be unaffected.

5. In resistance-limited reactors, power delivered to the load circuit is equal to power loss in the reactor winding. This is a reasonable, practical condition for small reactors.

6. Heat-dissipating surfaces dissipate heat at a uniform rate. By applying a uniform rate to only selected surfaces of the reactor, it is possible to approximate the condition in a practical reactor where the iron core is less effective in dissipating heat than the copper-winding surface.

Problem

To show in detail how the method was applied to a magnetic-amplifier problem, the details of optimizing the large thermally limited reactor are related in Appendix IV. This represents a problem that is extremely difficult to solve by regular mathematical techniques.

Presentation of General Magnetic-Amplifier Results

Thermally Limited Reactor— Maximum Output for Minimum Cost

From analysis in Appendix IV it is seen that the optimum shape for the reactor results in a very tall, elongated device. Fig. 1(A) shows the reactor shape drawn to scale. The reactor rating for which the power loss is 2.5 per cent calculates to be approximately 4 kw in the half-wave circuit. Considering the foregoing optimum unrealistic from the standpoint of proportions, the same problem can be solved restricting h/a to a value of 4 rather than the free value of 8. This is an arbitrary choice that is more appealing to the eyes and easier to build, mount, etc. The resulting configuration is shown in Fig. 1(B). These are proportions much more practical and the loss in optimum represents only 2.5 per cent of that achieved by the completely free solution.

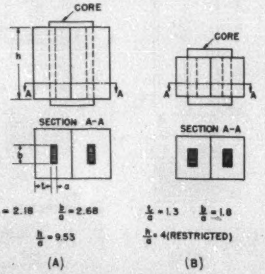

Fig. 3. Optimum core shape solutions for resistance-limited reactors

A—Free optimum
B—Restricted optimum

The optimum shown in Fig. 1 is not a sharply defined one. It is broad and flat. This is illustrated by the curves of Fig. 2 where the dimension ratios are varied one at a time from the full free optimum.

Resistance-Limited Reactors— Maximum Figure of Merit

An analysis of the resistance-limited reactor yielded a shape having a large window and thin leg. This shape is shown in Fig. 3(A). Maximum rating for this shape occurs when the size is large enough to encounter thermal limit. At 0.5 watt per square inch of surface, this is approximately a 6-watt output for the half-wave circuit.

Again the free optimum yields impractical proportions. By restricting h/a to a value of 4 rather than the free 9.53, a new optimum was obtained, as shown by Fig. 3(B). Maximum rating for this shape occurs at 3.5 watts half-wave. Optimum under this restriction has 8 per cent less merit than the free optimum. As in the thermally limited case, a broad flat optimum is seen to result for the resistance-limited case. This is shown in Fig. 4.

Continuing the resistance-limited analysis to toroids where the configuration of the winding is given an approximate trapezoidal form, an optimum is achieved such as shown in Fig. 5. Maximum rating for this reactor is approximately 3 watts.

Appendix I. Proof of the Method's Criterion

Let P and Q be the two characteristics that are important as design objectives in an optimization problem. Both P and Q are homogeneous polynomials and are appropriately described by the same dimensions, i.e., $l_1, l_2 \ldots l_n$

$$\begin{aligned} P &= P_1 + P_2 + \ldots P_s \\ &= (a_1 l_1^{\alpha_{11}} l_2^{\alpha_{21}} \ldots l_n^{\alpha_{n1}}) + (a_2 l_1^{\alpha_{12}} l_2^{\alpha_{22}} \ldots \\ &\qquad l_n^{\alpha_{n2}}) + \ldots (a_s l_1^{\alpha_{1s}} l_2^{\alpha_{2s}} \ldots l_n^{\alpha_{ns}}) \end{aligned} \qquad (27)$$

Vol.
Pt. 1
195

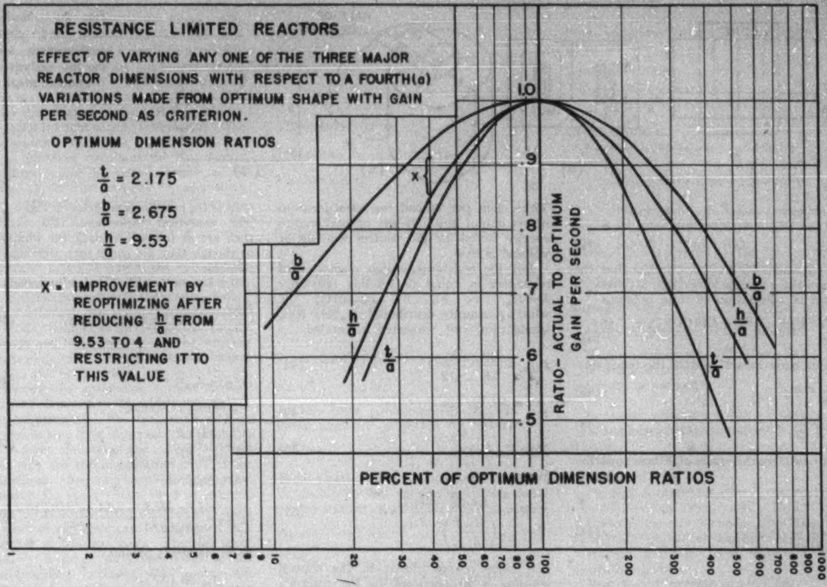

Fig. 4. Resistance-limited reactors

$$Q=Q_1+Q_2+Q_3\ldots Q_t=(b_1l_1^{\beta_{11}}l_2^{\beta_{21}}\ldots l_n^{\beta_{n1}})+(b_2l_1^{\beta_{12}}l_2^{\beta_{22}}\ldots l_n^{\beta_{n2}})+\ldots(b_tl_1^{\beta_{1t}}l_2^{\beta_{2t}}\ldots l_n^{\beta_{nt}}) \quad (28)$$

The first subscripts on the exponents indicate the particular dimension with which each is associated. The second subscript indicates the term of the polynomial in which it occurs. The polynomials being homogeneous

$$(\alpha_{11}+\alpha_{21}+\ldots\alpha_{n1})=(\alpha_{12}+\alpha_{22}+\ldots\alpha_{n2})=(\alpha_{1s}+a_{2s}+\ldots\alpha_{ns})=A \quad (29)$$

$$(\beta_{11}+\beta_{21}+\ldots\beta_{n1})=(\beta_{12}+\beta_{22}+\ldots\beta_{n2})=(\beta_{1t}+\beta_{2t}+\ldots\beta_{nt})=B \quad (30)$$

A is the power of linear dimension to which P is responsive. B is the power of linear dimension to which Q is responsive.

The criterion for the method states that at optimum shape application of infinitesimal per-unit increments to any one dimension l_p

$$\frac{\dfrac{\Delta P}{Pl_p}}{\dfrac{\Delta Q}{Ql_p}}=\frac{A}{B} \quad (31)$$

This can also be written as

$$\frac{\dfrac{1}{P}\dfrac{\partial P}{\partial l_p}\dfrac{dl_p}{l_p}l_p}{\dfrac{1}{Q}\dfrac{\partial Q}{\partial l_p}\dfrac{dl_p}{l_p}l_p}=\frac{A}{B}=\frac{\dfrac{1}{P}\dfrac{\partial P}{\partial l_p}}{\dfrac{1}{Q}\dfrac{\partial Q}{\partial l_p}} \quad (32)$$

To prove that equations 31 and 32 are true, solve the problem of maximizing P for a fixed value of Q. This will yield the same result if Q is minimized for a fixed value of P. Since Q is fixed

$$dQ=0=\sum_{p=1}^{p=n}\frac{\partial Q}{\partial l_p}dl_p \quad (33)$$

and since P is to be a maximum

$$dP=0=\sum_{p=1}^{p=n}\frac{\partial Q}{\partial l_p}dl_p \quad (34)$$

Thus, equations 33 and 34 are simultaneous equations of n variables of the form dl_p. For two such equations to be compatible, the ratios of the coefficients of like terms must all bear the same fixed value, i.e.

$$\frac{\dfrac{\partial P}{\partial l_p}}{\dfrac{\partial Q}{\partial l_p}}\equiv K \quad (35)$$

for any values of p from 1 to n.

Now apply this condition to the problem computing the partial derivatives from equations 27 and 28

$$\frac{\partial P}{\partial l_p}=\frac{\partial P_1}{\partial l_p}+\frac{\partial P_2}{\partial l_p}+\ldots\frac{\partial P_s}{\partial l_p} \quad (36)$$

From equation 27 it is apparent that this becomes

$$\frac{\partial P}{\partial l_p}=\frac{1}{l_p}(\alpha_{p1}P_1+\alpha_{p2}P_2+\ldots\alpha_{ps}P_s) \quad (37)$$

and similarly

$$\frac{\partial Q}{\partial l_p}=\frac{1}{l_p}(\beta_{p1}Q_1+\beta_{p2}Q_2+\ldots\beta_{pt}Q_t) \quad (38)$$

Substituting equations 37 and 38 into equation 35

$$\frac{1}{l_p}(\alpha_{p1}P_1+\alpha_{p2}P_2+\ldots\alpha_{ps}P_s)=K\frac{1}{l_p}(\beta_{p1}Q_1+\beta_{p2}Q_2+\ldots\beta_{pt}Q_t) \quad (39)$$

It is apparent that there are n such equations to be written, one for each value of p. If all n equations were added, the result is

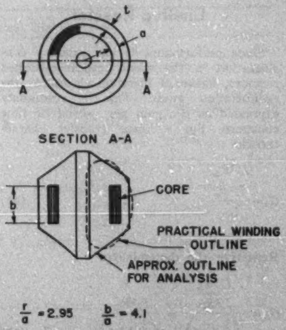

Fig. 5. Optimum core shape for resistance-limited toroidal reactor

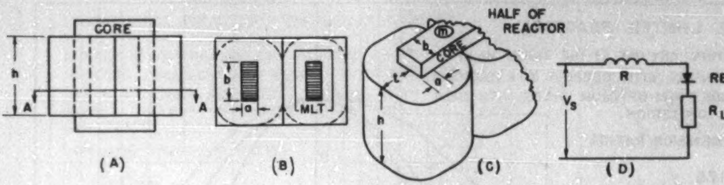

Fig. 6. Stacked core and circuit configurations used for the analysis of optimum shape

$$[(\alpha_{11}+\alpha_{12}+\ldots\alpha_{n1})P_1+\ldots(\alpha_{1s}+\alpha_{2s}+\ldots\alpha_{ns})P_s]=K[(\beta_{11}+\beta_{12}+\ldots\beta_{n1})Q_1+\ldots(\beta_{1t}+\beta_{2t}+\ldots\beta_{nt})Q_t] \quad (40)$$

But equations 29 and 30 stipulate that the sums of the α's and β's are equal to constants A and B. Equation 40 then becomes

$$A(P_1+P_2+\ldots P_s)=KB(Q_1+Q_2+\ldots Q_t) \quad (41)$$

From equations 27 and 28 this becomes

$$AP=KBQ \quad (42)$$

$$K=\frac{A}{B}\frac{P}{Q} \quad (43)$$

Substituting this value of K into equation 35

$$\frac{\frac{\partial P}{\partial l_p}}{\frac{\partial Q}{\partial l_p}}=\frac{A}{B}\frac{P}{Q} \quad (44)$$

or

$$\frac{\frac{1}{P}\frac{P}{\partial l_p}}{\frac{1}{Q}\frac{\partial Q}{\partial l_p}}=\frac{A}{B} \quad (45)$$

Thus, the method criterion as expressed by equations 31 and 32 is confirmed by the conventional solution of the problem on a generalized basis.

Appendix II. Optimization Parameters and Current Density Relationships for the Resistance-Limited Reactor

Since performance is the primary consideration in the small resistance-limited reactors, figure of merit is chosen as the optimization guide. This is commonly expressed as d-c gain per second of time constant. For a linear transfer characteristic

$$G_s=\frac{\frac{I_L^2R_L}{I_c^2R_c}}{\frac{L_c}{R_c}} \quad (46)$$

Rewriting the denominator

$$G_s=\frac{\frac{I_L^2R_L}{I_c^2R_c}}{2\left(\frac{\frac{1}{2}LI_c^2}{I_c^2R_c}\right)}=\frac{I_L^2R_L}{2\left(\frac{1}{2}LI_c^2\right)} \quad (47)$$

Thus, gain per second is proportional to power output and inversely proportional to energy stored in the control winding or volume of iron.

For the resistance-limited reactor, load resistance is equal to winding resistance $R=R_L$; see Fig. 6. Considering the windings equally distributed on both legs, single turn, and connected in parallel

$$I_{L\text{rms}}=\frac{V_{s\text{rms}}}{2R}\frac{1}{\sqrt{2}} \quad (48)$$

$$R=\frac{\rho(MLT)}{A_{ca}(SF)} \quad (49)$$

$$V_s=K_b(A_{fe}) \quad (50)$$

Hence

$$I_L^2R_L\propto\frac{(A_{fe})^2}{\left(\frac{MLT}{A_{ca}}\right)^2}\frac{MLT}{A_{ca}}\propto l^3 \quad (51)$$

and since energy stored in the control winding is proportional to the reactor's volume of iron

$$2\left(\frac{1}{2}LI_c^2\right)\propto l^3 \quad (52)$$

These are the powers to which the optimizing parameters are responsive.

Expressing load current and current density in terms of the physical dimensions

$$V_s=K_b(A_{fe})=K_bab \quad (53)$$

$$MLT=2a+2b+4t \quad (54)$$

$$A_{ca}=2th \quad (55)$$

$$I_{L\text{rms}}=\frac{K_b(SF)}{\rho\sqrt{2}}\frac{ab\,th}{2a+2b+4t}\propto l^3 \quad (56)$$

$$i_{a\text{rms}}=\frac{I_{L\text{rms}}}{A_{ca}}=\frac{K_b(SF)}{2\sqrt{2}\rho}\frac{ab}{2a+2b+4t} \quad (57)$$

Appendix III. Current Density Relationships in Large Thermally Limited Reactors

In the large thermally limited reactor with power winding equally distributed on both legs, it is recognized that the iron is less effective as a heat-dissipating surface than the exposed sides of the windings. This is true for heat generated in the windings because of the usual heavy insulation between the winding and core. The heat generated in the iron does not govern the design so it is neglected. To approximate this condition, all exposed surfaces of the windings are assumed to reject heat at 1/2 watt per square inch whereas the same is assumed for only the top and bottom ends of the punchings *m* circled in Fig. 6(C). The analytical expressions that evolve then are as follows, treating the windings as though they are single turn windings in parallel:

For constant watts per unit of surface

$$\frac{I_L^2R_w}{A_s}=K\leqq 0.5 \text{ watt per inches}^2 \quad (58)$$

Load current

$$I_L^2=(i_aA_{ca})^2 \quad (59)$$

Winding resistance

$$R_w=\frac{\rho(MLT)}{A_{ca}(SF)} \quad (60)$$

Winding loss

$$I_L^2R_w=\frac{I_L^2\rho(MLT)}{A_{ca}(SF)}=\frac{i_a^2A_{ca}\rho(MLT)}{(SF)} \quad (61)$$

From equations 58 and 61

$$I_L^2=\frac{A_{ca}KA_s(SF)}{\rho(MLT)} \quad (62)$$

also

$$i_a^2=\frac{KA_s(SF)}{A_{ca}\rho(MLT)}=\frac{K(SF)}{\rho}\frac{A_s}{Q_{ca}} \quad (63)$$

$$\frac{i_a^2Q_{ca}}{A_s}\frac{\rho}{(SF)}=K\propto\frac{i_a^2Q_{ca}}{A_s} \quad (64)$$

Reducing equations 62 and 63 to linear dimension relationships

$$I_L\propto l^{1.5} \quad (65)$$

$$i_a\propto l^{-0.5} \quad (66)$$

From reactor dimensions

$$MLT=2a+2b+\pi t \quad (67)$$

$$A_{ca}=2th \quad (68)$$

$$A_s=4ah+2hb+4\pi ht+4ab+8at+8bt+4\pi t^2 \quad (69)$$

Substituting these dimensional relations into equations 62 and 63

$$I_L^2=\frac{2K(SF)}{\rho}\frac{th}{2a+2b+\pi t}[4ah+2hb+4\pi ht+4ab+8at+8bt+4\pi t^2] \quad (70)$$

$$i_a^2=\frac{K(SF)}{\rho}\frac{[\ ]}{2th(2a+2b+\pi t)} \quad (71)$$

Appendix IV. Problem: Optimize the Large Thermally Limited Reactor

For simplicity of analysis the half-wave amplistat circuit of Fig. 6(D) will be used.

The reactor will be of a general configuration as shown in the same figure. The winding is equally divided between both legs, and is considered a single-turn winding and the two sections are treated as though connected in parallel. The control winding is made as small as practically possible under the design objective of this problem—the space it might occupy is neglected. The configuration need not digress from this for a full wave circuit as the two control windings would be simply connected in series. From the previous considerations, the optimum for the large thermally limited reactor should be based on the maximum power output for a given cost of materials.

Output rating is simply the volt-ampere product in the load. With the condition of negligible power loss in the power winding for economical operation, the output can be simply defined as the product of supply voltage and load current, i.e., the winding loss is neglected in computing power output but is the fundamental parameter in determining the maximum current density (surface dissipation) at which the reactor can be operated. The dissipation surface, as can be seen from Appendix III, includes all exposed surfaces of the copper windings and only the top and bottom ends of the punchings. Any surfaces deemed most realistic for the problem may be selected and will effect optimum shape accordingly.

Cost of materials can be expressed in a number of different ways. For this problem, it is taken as proportional to the parallelepiped enclosing the reactor—the product of the three maximum dimensions along the three major axes. This assumes that labor costs are directly proportional to material cost, copper has the same price per pound as the iron punchings, and that the extra volume of the parallelepiped represents the extra costs of mounting brackets, covers, and terminals. These are reasonable conditions for the large reactor but would not be so for the small reactors.

First develop the expressions for power output and cost volume: the power output

$$P_o \cong P_i = V_s I_L \qquad (72)$$

From the generated voltage expression

$$E_{rms} = \frac{2\pi}{\sqrt{2}} f N B_{max} A_{fe} \times 10^{-8} \text{ volts} \qquad (73)$$

it is apparent for this problem that f, N, and B_{max} are constant so that

$$V_s \propto A_{fe} = ab \qquad (74)$$

Current is established from equation 59

$$I_L = i_a A_{ca} \qquad (75)$$

Current density from equation 64

$$i_a = \left(\frac{K(SF)}{\rho} \frac{A_s}{Q_{ca}} \right)^{1/2} \qquad (76)$$

and in terms of reactor demensions, Fig. 6(C) and Appendix III

$$A_s = 4ah + 2hb + 4\pi ht + 4ab + 8at + 8bt + 4\pi t^2 \qquad (77)$$

$$Q_{ca} = A_{ca}(MLT) = 2th\,(2a + 2b + \pi t) \qquad (78)$$

Since

$$A_{ca} = 2th \qquad (79)$$

$$(MLT) = 2a + 2b + \pi t \qquad (80)$$

So from equations 72, 75, 76, and 79, power output

$$P_i \propto abthi_a \qquad (81)$$

Enclosure volume

$$\text{Height} = h + 2a \qquad (82)$$

$$\text{Width} = 2a + 4t \qquad (83)$$

$$\text{Depth} = b + 2t \qquad (84)$$

$$\text{Enclosure volume } Q_t = (h + 2a)(2a + 4t) \times (b + 2t) \qquad (85)$$

Second, establish the linear dimension relationships:
From equation 65

$$I_L \propto l^{1.5} \qquad (86)$$

From equation 74 it is apparent that

$$V_s \propto l^2 \qquad (87)$$

Then from equations 72, 86, and 87, power input (or output) is

$$P_i \propto l^{3.5} \qquad (88)$$

From equation 85 it is apparent that cost or parallelepiped volume is proportional to the product of three dimensions, hence

$$Q_t \propto l^3 \qquad (89)$$

Third, assume a shape (three ratios of the four dimensions) from whatever design history or experience is available and apply increments in turn to each individual dimension and see how closely the ratio of increments in power output and cost of enclosure volume follow the 3.5-to-3 law. When the correct shape is found, applying per-unit increments to any dimension will yield resulting per-unit increments in this ratio.

Assumed shape

$$a = 4t \qquad (90)$$

$$b = 2a = 8t \qquad (91)$$

$$h = 8a = 4b = 32t \qquad (92)$$

From equations 78 and 77 using equations 90 to 92

Winding volume

$$Q_{ca} = 2th(2a + 2b + \pi t) \qquad (93)$$
$$= 64t^2(8t + 16t + \pi t) = 1737t^3$$

Cooling surface

$$A_s = 4ah + 2hb + 4\pi ht + 4ab + 8at + 8bt + 4\pi t^2 \qquad (94)$$
$$= (512 + 492 + 128\pi + 128 + 32 + 64 + 4\pi)t^2$$

$$\text{Height} = h + 2a = (32 + 8)t = 40t \qquad (95)$$

$$\text{Width} = 2a + 4t = (8 + 4)t = 12t \qquad (96)$$

$$\text{Depth} = b + 2t = (8 + 12)t = 10t \qquad (97)$$

$$\text{Rating} \propto abthi_a \qquad (98)$$

Apply 1u increase to h dimension:

Height increase = 1×32/40 = 0.8u
Width unchanged = 0
Depth unchanged = 0

Enclosure volume increase = 0.8u

Rating increase then should = 0.8×3.5/3 = 0.933u.

Now winding volume increase from equation 93 = 1u.

Cooling surface increase from equation 94 = (512+492+128π)/1,642×1 = 0.856u.

Current density increase from equation 76 = (0.856−1)1/2 or decreases 0.072u.

Rating increase from equation 98 = 1−0.072 = 0.928u.

But desired increase was 0.933u.

The h increment increased rating 0.928/0.933 = 0.9464 times that desired. It is concluded that h is slightly too large with respect to other dimensions.

Apply 1u increase to b dimension by a sequence similar to the aforementioned. This b increment increased rating 0.9135/0.933 = 0.9791 times that desired. It is concluded that b is too large with respect to the other dimensions.

Apply 1u increase to t dimension by a sequence similar to the aforementioned. The t increment increased rating 0.579/

Table I. Per Unit of Desired Increase in Rating Resulting from Increments in h, b, t, and a

Trial	Dimension and Trial Equivalent							
	h	h_{eq}	b	b_{eq}	t	t_{eq}	a	a_{eq}
1	0.9464		0.9791	$h/4$	0.9325	$h/32$	1.0455	$h/8$
		$4b$				$b/8$		$b/2$
	h too large	$32t$	b too large	$8t$	t too large		a too small	$4t$
		$8a$		$2a$		$a/4$		
2	1.02		1.015	$h/4$	0.936	$h/28$	1.0154	$h/7$
		$4b$				$b/7$		$\frac{4}{7}b$
	h too small	$28t$	b too small	$7t$	t too large		a too small	$4t$
		$7a$		$\frac{7a}{4}$		$a/4$		
3	1.0397		1.00548	$\frac{7.3}{8(4.5)}h$	0.9765	$h/36$	1.0092	$h/8$
		$\frac{8(4.5)}{7.3}b$						$\frac{4.5}{7.3}b$
	h too small	$36t$	b too small	$7.3t$	t too large	$\frac{b}{(7.3)2}$	a too small	$4.5t$
		$8a$		$\frac{7.3}{4.5}a$		$a/4.5$		

0.621 = 0.9325 times that desired. It is concluded that *t* is too large with respect to the other dimensions.

Apply 1u increase to *a* dimension by a sequence similar to the aforementioned. The *a* increment increased rating 1.057/1.011 = 1.0455 times that desired. It is concluded that *a* is too small with respect to the other dimensions.

Fourth, the results of the first trial are tabulated in Table I along with the assumed ratios in the form of h_{eq} values. With the assumed ratios and resulting per-unit (of desired) increment thus logged for ready review, the next trial can be easily formulated and evaluated. For a new assumed shape, similar to equations 90 to 92, it is necessary to prepare another group of equations similar to equations 93 through 98.

Fifth, the process is repeated and, finally after a few trial, the resulting per-unit increase in rating is sufficiently close to the desired one so that the last assumed shape can be accepted as the answer.

Determination of Thermal Life of Enameled Wire by Laboratory Methods

F. A. SATTLER
NONMEMBER AIEE

A THERMAL life test which will give quick results is a desirable feature in wire enamel development. Since it may be necessary to screen many formulations, it is desirable that this test be convenient to run. Four criteria for thermal life determination are briefly reviewed. These are as follows: 1. visual inspection of thermally aged coils; 2. flexibility of aged enameled wire; 3. decrease in film thickness with aging; and 4. dielectric breakdown of aged dielectric twist samples. In each test the enameled wire samples are aged in air-circulating ovens and the life is determined at temperatures of 100 to 300 degrees centigrade (C). Some data obtained from these tests are presented.

Visual Inspection Test

In this test a 15-inch length of enameled wire is wrapped around a 5/8-inch mandrel, removed from the mandrel, and identified with an aluminum tag. The 5/8-inch mandrel is convenient to handle and is large enough to eliminate heat-shock failure for most materials. Heat-shock failure is the cracking of an enamel film caused by a combination of film strain and short-time heating. The resulting coil is shown in Fig. 1.

Each coil is aged at a specific temperature in an open glass container in an air-circulating oven along with other samples. The coils are examined periodically at 22.5×magnification. Failure is evidenced by general crazing, cracking, or flaking. A typical crazing pattern is shown in Fig. 2.

When failure occurs by flaking, the end point is not as sharp and is more difficult to determine. The failure point from flaking has arbitrarily been set as the time at which five large flaws or ten small flaws are seen on the sample.

In Fig. 3, a plot of log life versus reciprocal of absolute temperature[1] is given for Formvar, enamel *A* (organic enamel) and enamel *B* (modified silicone), all on no. 18 American Wire Gauge copper wire. The failure points fall along a straight line for most materials at temperatures below 200 C, but the slope generally falls off at the higher temperatures.

Wire sizes nos. 20 to 15 American Wire Gauge have given fairly reproducible results in this test. The small wire sizes, no. 26 American Wire Gauge and smaller, have been observed to show an appreciably longer life than the larger wire with the same enamel. There is no clear-cut explanation for this phenomenon at the present time. Frequency of observation (thermal cycling) and coil diameter have been observed to have little effect on the thermal life results in this test.

This method can also be used to study impregnating varnish-wire enamel combinations. The enameled wire coils are dipped in the varnishes and baked out before aging. In Fig. 4, note that Formvar appears to be unaided thermally by a silicone impregnating varnish, but is improved appreciably by a phenolic impregnating varnish. Enamel *A*, on the other hand, develops thermal cracks more readily with a phenolic varnish impregnant than does the unimpregnated enameled wire, while a silicone impregnant improves thermal life by a factor of four.

The visual inspection test has also been used in testing sealed, air-excluded systems such as enameled wire in transformer oil, or in Freon-oil mixtures. Fig. 5 shows two samples of enameled wire sealed in vacuo in transformer oil in a glass tube. A sample of Formvar in this test is flawless after 495 days at 175 C, while an air-exposed sample of Formvar crazes in about 30 days at 175 C.

The visual inspection test may give misleading results, especially at temperatures above 200 C. Some enamel films retain a good appearance while evaporating rapidly, leaving very little insulation. Another disadvantage is the personal element involved in determining the end point. On the other hand, the test is very easily set up and readily shows up large differences in thermal stabilities.

Flexibility Test

While the low temperature data are considered the most reliable and most im-

portant in the previously described static life test, it is not always expedient to await such data. Thus a flex-life test may show the trend of degradation of the film long before it is realized in a static life test.

In this flexibility test, straight pieces of enameled wire are aged in open glass tubes in ovens at temperatures in the range of 100 to 200 C. The flexibility retention is determined periodically by winding on graduated mandrels. In Fig. 6, per-cent elongation to failure is plotted against aging time at 200 C for several enamels. It is difficult to interpret the data in terms of expected life, but some background is being obtained on this test. The method cannot be used in studying wire enamel impregnating varnish combinations.

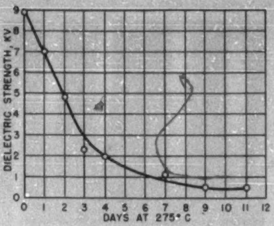

Fig. 10 (right). Dielectric strength in kilovolts versus days at 275 C. Enamel B silicone impregnated

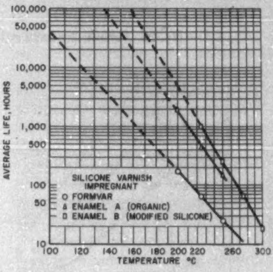

Fig. 11 (right). Dielectric twist life in hours (1,000 volts) versus temperature in C

Decrease in Film Thickness

In this test, the reduction in film thickness of an enameled wire sample, as measured with micrometer calipers, is recorded at intervals as the straight piece of wire is aged at an elevated temperature. This is similar to a weight loss test and may be considered less accurate. However, in the weight loss test it is difficult to simulate the enameled wire film in such factors as baking out low molecular weight polymers, thickness of film, and effect of metal substrate. With careful caliper measurements, a fairly accurate picture may be obtained on the film thickness retention, and such comparison of various enameled wires is informative.

In Fig. 7, the per-cent decrease in film thickness is plotted against aging time at 175 C for two enameled wire samples. A disadvantage of this test is that it cannot be used for enameled wire impregnating varnish combinations.

Dielectric Breakdown Test

In this test, a standard dielectric twist sample, Fig. 8, is aged at a given temperature and tested periodically at a specific voltage until breakdown occurs. Ten to 25 samples, placed in a glass container, are used to determine the average life of an enamel at each temperature. Impregnating varnish wire enamel combinations are readily tested in this procedure by dipping the twist sample and baking. In Fig. 9, the life-temperature curve is shown for Formvar enameled wire of no. 18 American Wire Gauge with no impregnation, silicone varnish impregnation, and phenolic varnish impregnation. It should be noted that the silicone varnish impregnation improves the life of the Formvar but not to the extent that the phenolic varnish does. This partially verifies the results of the visual inspection test.

The voltage failure criterion has been varied in this test over a range of 500 to 3,000 volts. Some enameled wire samples tend to approach 500 volts almost asymptotically when aged, Fig. 10, giving a wide distribution of failure points. A 1,000-volt failure criterion has been used with satisfactory results on nos. 17 and 18 American Wire Gauge wires. Fig. 11 shows dielectric twist life in hours versus temperature. A distribution curve for 1,000-volt failures at 250 C is shown in Fig. 12.

It has been observed that frequency of thermal cycling has a definite effect on the results obtained, and frequency of observation at each temperature must be fairly well standardized to obtain consistent results. An observation period of about one-tenth the expected life has been used for most materials.

The low temperature failure data are again considered the most important. In comparing various experimental enamels it has been found advantageous to plot actual dielectric breakdown values versus time at 200 C to obtain a quicker picture of the degree of degradation taking place at this comparatively low temperature.

Of the four methods described, the dielectric breakdown criterion is considered the best method of thermal life evaluation. However, the other three methods help to complete the picture and allow more definite conclusions to be drawn.

A comparison of the thermal life data of Formvar enameled wire as determined by visual inspection, dielectric breakdown, and accelerated motor testing[2] is shown in Fig. 13. The motor data curve

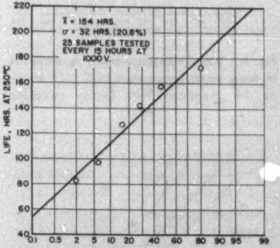

Fig. 12. Probability plot of dielectric twist failures

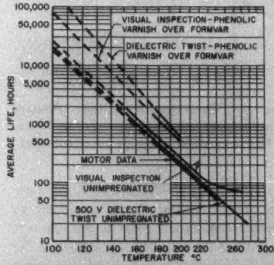

Fig. 13. Average life in hours versus temperature in C. Comparison of Formvar life estimated in various tests

Vol
Pt.
195

is low, especially as the Formvar enameled wire in the motor was impregnated with a phenolic varnish. However, the motor test involved severe vibration and humidity cycling superimposed upon thermal degradation.

Conclusions

The four criteria discussed for evaluating thermal stability of enameled wire, namely, visual inspection, flexibility, film thickness measurement, and dielectric breakdown, give a picture of the rate and type of degradation taking place when enameled wire is aged thermally. Data from the visual inspection test and dielectric breakdown test can be plotted on log life versus reciprocal of absolute temperature graphs to estimate practical operating temperatures of the enameled wires. Results from these tests show the same temperature dependence as motor life tests. Impregnating varnish wire enamel combinations can also be evaluated using the visual inspection and dielectric breakdown methods.

An Automatic Field Plotter

F. B. TUTEUR
ASSOCIATE MEMBER AIEE

Synopsis: Solutions of field problems can often be approximately obtained by constructing a 2-dimensional model of the field to be studied in an electrolytic tank. A servomechanism is described which is arranged to follow the equipotential lines that exist in such a model and to plot them automatically. A rotating co-ordinate system is employed to enable the device to trace out closed curves and other multivalued functions. This co-ordinate system is automatically aligned with the equipotential lines to be followed so that the sweep velocity is constant and parallel to the desired curve and correction velocity is normal to this curve. The system is analyzed with particular emphasis on stability and accuracy. The prototype plotter was able to follow curves with a minimum radius of $^1/_2$ inch and maintain an accuracy of 0.5 per cent of maximum travel.

AN analogue method commonly used in the solution of field problems involving Laplace's equation in two dimensions is the electrolytic tank. In its simplest form such a tank consists of a shallow basin of large area in the center of which the boundaries of the problem to be studied are placed in the form of electrodes that are connected to a fixed voltage source. If the area of the tank is sufficiently large, it is possible to ignore the edge effects introduced by the finite extent of the conducting medium. The solution to the problem is obtained in the form of equipotential lines which may be determined by direct measurement, and which may then be plotted. When a large number of points are to be located, this process is apt to become rather tedious, and automatic plotting becomes desirable.

Several improvements in the basic technique have been made in recent years. An improved arrangement of the tank itself was described by Boothroyd, Cherry, and Makar.[1] Their tank consists essentially of two conducting circular surfaces, placed back to back separated by an insulator and joined at the circumference. It can be shown that this configuration represents a transformation of an infinite conducting plane into a finite area; hence, it permits accurate analogues to be set up in small tanks with only negligible edge effects. An automatic plotter was described by Green,[2] but it suffers from the disadvantage that it cannot plot multivalued functions easily. The device described in this paper overcomes this disadvantage, and incorporates a variable gain feature that permits dependable operation over wide variations of potential gradient. J. K. Mickelson[3] described a device which handles multivalued functions and appears to be very similar to the one described here.

Elementary Theory of Operation

Assume that it has been possible to set up an electric analogue of a particular field problem by means of a plane of resistive conducting material with the proper boundaries and electrodes. With such an arrangement, the lines of constant voltage correspond to equipotential lines of the problem. The solution can be obtained by plotting selected equipotential lines e.g., all lines with integral values of voltage in the region of interest. The system constructed used an electrolytic tank as the conducting surface; however, the techniques to be described are equally applicable to any conducting surface.

The voltage at any position of the operating plane can be picked up with a probe and compared with a reference voltage. The voltage difference or error can be used in a servo system to correct the probe position to the desired line on the plane. For example, let the rectangular co-ordinates x and y be assigned to the surface of the tank and assume the equipotential lines are single-valued in y. If a constant velocity is applied in the x direction and the servo loop has freedom in the y direction, the probe will trace out the desired equipotential line.

With a constant sweep speed, the velocity of the probe along the curve will not in general be constant but will vary with the slope of the curve. The velocity can be found as follows

$ds=\sqrt{(dx)^2+(dy)^2}$ = infinitesimal distance along the curve

$$\dot{s}=\sqrt{\dot{x}^2+\left(\frac{dy}{dx}\dot{x}\right)^2}=\dot{x}\sqrt{1+\left(\frac{dy}{dx}\right)^2} \qquad (1)$$

From equation 1, it can be seen that, as the curve becomes parallel to the y axis, the tracing speed must become very large. This places an extremely high response speed demand on the servo loop. It is also important to notice that this system is incapable of plotting curves multivalued in y. A method will now be

The authors wish to acknowledge the assistance of Prof. P. M. Schultheiss who helped in the solution of many of the design problems encountered in this development. Particular thanks are also due to S. C. Bogan who first suggested the method of continuously varying the alignment of the auxiliary co-ordinate system.

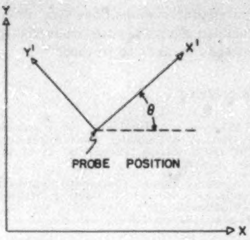

Fig. 1. Rotated co-ordinate system

described which will overcome these limitations.

Consider a new rectangular co-ordinate system having $x'-y'$ axes centered at the probe and rotated so that the x' axis makes an angle θ with the x axis; see Fig. 1. Let the sweep velocity be applied in the x' direction and let the servo system operate in the y' direction. Supposing that the angle θ between the two co-ordinate systems is manually adjustable, then a human operator watching the progress of the probe through the electrolyte would be able to keep always the x' axis, and thus the sweep direction, parallel to the equipotential line being followed. In this way, the tracing velocity could be maintained constant and there would be no difficulty in the following of multivalued lines since all lines would be single-valued in the neighborhood of the probe.

In practice it is difficult to rotate the co-ordinate axes physically, and it is therefore desirable to control the probes along a fixed set of axes, yet retain the flexibility of the rotating co-ordinate system. This end may be achieved by the use of two resolvers connected as shown in Fig. 2. The operation of these resolvers is, perhaps, best understood by assuming, for the time being, that the error voltage V_e and the angle θ are both zero. Under these conditions, the sweep voltage is applied to the x axis drive motor only and the probe moves parallel to the x axis at sweep speed. If the input shaft of the resolver is now rotated in the positive direction, the x axis motor receives a smaller voltage $V_s \cos \theta$ and the y axis motor receives the voltage $V_s \sin \theta$. The result is that the probe moves in the new direction θ but still with the same sweep speed. If the error voltage is also applied, the probe acquires a component of velocity perpendicular to the sweep velocity. The way in which all four velocity vectors add to give the final probe velocity is shown in Fig. 3, where S_x and S_y represent the sweep velocity components and C_x and C_y the correction velocity components in the x and y direction respectively.

The adjustment of the angle θ, supposed to require a human operator, may, of course, be made automatically. If an auxiliary probe is mounted near the main probe described previously, a voltage will exist between these two probes unless they are both located on the same equipotential line. This voltage may be used as the input to a servomechanism which will rotate the two probes so that they are always on the same equipotential line and, at the same time, vary the shaft angle of the resolvers. The adjustment of this angle will not, in general, be completely exact, particularly in regions where the equipotential lines are sharply curved; however, by spacing the two probes very closely together ($^1/_2$ inch or less), satisfactory performance may be obtained.

Description of the Experimental System

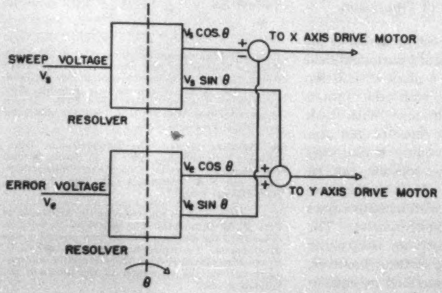
The two probes described must be continuously aligned and positioned in an electrolytic tank used as the resistive plane. The alignment is accomplished by means of a drive motor geared to a polystyrene rotor in which the probes are mounted; probe voltages are picked off by slip rings. A selsyn attached to the rotor shaft is used to sense the angular alignment of the probes. This entire assembly is mounted on a carriage, Fig. 4, which rides on a crossarm. The carriage is positioned by a cable from the y axis drive motor, while another cable from the x axis motor moves the crossarm along the two parallel supporting rails, see Fig. 5.

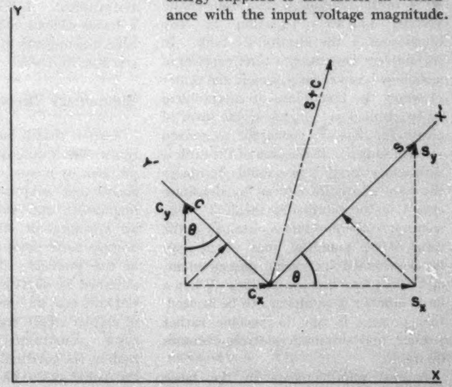
The resolvers required to transform the sweep and error voltages into the appropriate x and y components may either be mounted on the carriage and geared directly to the probe, or they may be mounted externally and driven by an electromechanical follow-up loop. The latter method was chosen so as to keep carriage size and weight down to a minimum. A selsyn, geared to the input shaft of the resolvers, is used with the selsyn coupled to the probe-turning motor in a conventional servomechanism which positions the resolvers in accordance with the probe angle.

The drive motors are 27-volt high-speed units with built-in gear boxes giving an output no-load speed of 250 rpm. These units were removed from a war-surplus *B-29* gun computer, as were the relay power amplifiers used to drive them. The relay amplifiers have an internal feedback arrangement which modulates the pulse width and repetition rate of the energy supplied to the motor in accordance with the input voltage magnitude.

Fig. 2 (below). Resolver connections

Fig. 3 (right). Velocity components





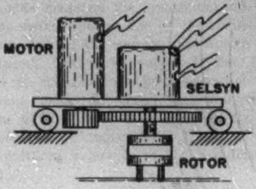


Fig. 4. Carriage assembly

Fig. 5. Carriage, crossarm, supporting rails, and electrolytic tank

The output-versus-input curve was found to be essentially linear between a dead-band region and saturation. The system loop gain is proportioned so that the dead-band referred to the pickup probes gives an error within the desired accuracy limits.

The resolvers are selsyns, also removed from the gunsight computer. Orthogonal trigonometric functions are obtained from the output by means of a resistive network; see Appendix I. The two resolvers, probe position selsyn, and resolver-control drive motor are mounted on a single chassis and coupled together by gears.

A-c amplifiers, cathode followers, and discriminators round out the components required. High-gain d-c amplifiers were avoided by using a 400-cycle carrier system and demodulating at a high-voltage level just ahead of the equalizer networks which feed the power amplifiers. The electrolytic tank used was modeled after the unit described by Boothroyd, Cherry, and Makar[1] to minimize edge effects.

Design Considerations

A block diagram of the complete system is shown in Fig. 6. The system has two input adjustments; the reference voltage V_r which selects the desired equipotential line, and the sweep voltage V_s which determines the sweep speed of the probe. Four different motors must be controlled: the two that move the carriage along the x and y axes, the motor which regulates the angle θ between the rotating $x'y'$ co-ordinate system and the fixed reference, and the follow-up motor that rotates the resolvers. Since the servomechanism controlling the angle θ is in many ways the heart of the system, it will be considered first. This servomechanism will be called the θ loop.

As shown in Fig. 7, the correct angle of alignment of the x' axis, ϕ, is the angle between the tangent to the desired curve and the x axis. This angle is determined approximately by the two probes referred to earlier. If the angle between a line drawn through the two probes and the x axis is called θ, then on the assumption of a uniform potential gradient the voltage between the probes is

$$e_\theta = KE\sin(\phi-\theta) \qquad (2)$$

where E is the voltage gradient, and K is a proportionality constant which depends on probe spacing and the dimensional units used. The difference between ϕ and θ is small if the θ loop operates properly so that equation 2 may be written approximately as

$$e_\theta \cong KE(\phi-\theta) \qquad (3)$$

If the gain of the amplifier in the θ loop is G_θ, then, in Laplace transform notation

$$\theta(s) = G_\theta H_\theta(s) e_\theta(s) \qquad (4)$$

where $H_\theta(s)$ stands for the frequency-sensitive elements in the θ drive system and represents equalizing networks, filters, and the drive motor. The negative of the loop gain of the θ loop is therefore

$$A_\theta(s) = KE\,G_\theta H_\theta(s) \qquad (5)$$

Note that the potential gradient E enters directly into this expression; this point will be considered in more detail later.

The θ loop is a standard unity-ratio feedback loop which takes the input ϕ and delivers the output θ. Hence, the well-known result

$$\theta(s) = \frac{A_\theta(s)\phi(s)}{1+A_\theta(s)} = \frac{KE\,G_\theta H_\theta(s)\phi(s)}{1+KE\,G_\theta H_\theta(s)} \qquad (6)$$

The follow-up loop that is required to rotate the resolvers is entirely conventional and requires no special comment. In the subsequent analysis it is assumed to be a perfect servo, i.e., the shaft position of the resolvers is always identically equal to θ the probe angle.

The remaining loop is required to move the probe designated as the "main probe" to the desired equipotential line. The voltage picked up by this probe is subtracted from the reference voltage V_r, and the difference $e_{y'}$ represents the error in main probe position. This voltage will be directly proportional to the perpendicular distance between the desired line and the main probe—assuming constant gradient, see Fig. 8. Thus, the error voltage will be $e_{y'} = E\Delta n$ where Δn is the perpendicular distance from the desired voltage line to the main probe. If $\Delta y'$ is the position error in the y' loop,

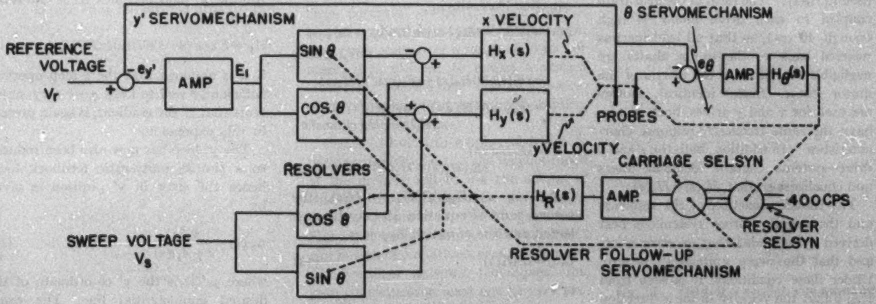

Fig. 6. System block diagram

1, 74
1
55

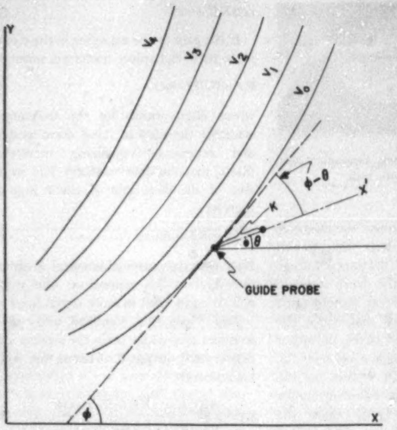

Fig. 7 (above). Correct angle of alignment of the x′ axis

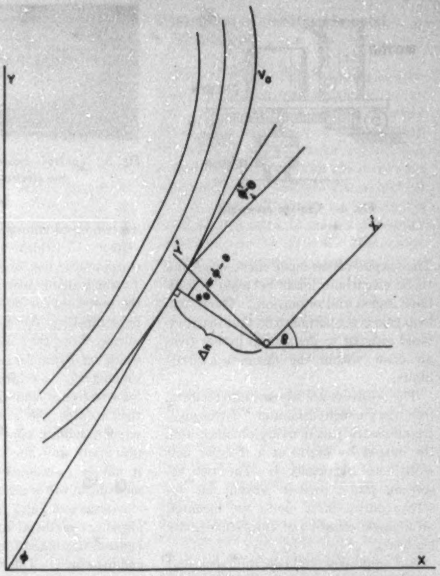
Fig. 8 (right). Effect of misalignment of x′ axis



Vol.
Pt. 1
1955

i.e., the distance between the main probe and the desired equipotential line as measured along the y' axis, then

$$\Delta n = \Delta y' \cos(\phi-\theta) \qquad (7)$$

and

$$e_{y'} = E\cos(\phi-\theta)\Delta y' \qquad (8)$$

Note that the error voltage in the y' loop is a function of the error in the θ loop; if $\phi-\theta$ is greater than $\pm\pi/2$ radians, the y' loop becomes unstable. Hence, the error in the θ loop must be kept small for proper operation of the y' loop.

The error voltage $e_{y'}$ is amplified, passed through the resolvers, and is then applied to $H_x(s)$ and $H_y(s)$ which represent the frequency-sensitive element of the x and y drive systems similar to those used in $H_\theta(s)$. The ratio of the gear train coupled to each drive motor is high enough, 40 to 1, so that all load inertias referred back to the motor shafts are negligible compared to the inertia of the motor rotor. Since identical motors are used for x and y drives, both motors have the same frequency-response characteristics. In addition, both the x and y drive systems contain identical filters and equalizers so that $H_x(s)=H_y(s)$.

The transfer function of the resolvers and the x and y drive systems is best derived by assuming that an error exists and that the sweep voltage V_s is zero. Under these conditions, it is seen from Fig. 6 that the velocity in the x direction is

$$C_x(s) = -sE_1H_x(s)\sin\theta \qquad (9)$$

and the velocity in the y direction is

$$C_y(s) = sE_1H_y(s)\cos\theta \qquad (10)$$

The extra s in these expressions is required to make the definitions for $H_x(s)$ and $H_y(s)$ consistent with that already adopted for $H_\theta(s)$. Reference to Fig. 3 indicates that the components in the y' axis of C_x and C_y are $-C_x\sin\theta$ and $C_y\cos\theta$ respectively so that

$$C(s) = sy'(s) = -C_x(s)\sin\theta + C_y(s)\cos\theta \qquad (11)$$

Substituting equation 9 and 10 into equation 11 results in

$$\begin{aligned} C(s) = sy'(s) &= sE_1(-\sin\theta)H_x(s)(-\sin\theta) + sE_1(\cos\theta)H_y(s)\cos\theta \\ &= sE_1(\sin^2\theta)H_x(s) + sE_1(\cos^2\theta)H_y(s) \\ &= sE_1\{\sin^2\theta H_x(s) + \cos^2\theta H_x(s) + [H_y(s)-H_x(s)]\cos^2\theta\} \\ &= sE_1H_x(s) + sE_1[H_y(s)-H_x(s)]\cos^2\theta \end{aligned} \qquad (12)$$

A long as $H_x(s) \cong H_y(s) = H(s)$, the second term of equation 12 may be neglected and the equation becomes

$$C(s) = sE_1H(s) \qquad (13)$$

or

$$y'(s) = E_1H(s) \qquad (14)$$

Since E_1 is proportional to the error in probe position, the velocity of the probe in a direction normal to the desired line is proportional to the magnitude of the error. It can, incidentally, be shown in a similar manner that the tangential velocity of the probe can be expressed by

$$S(s) = sV_sH(s) \qquad (15)$$

Thus the sweep and error-correcting functions take place independently even though both drive motors handle these two functions simultaneously.

If the gain of the amplifier in the y' loop is equal to $G=E_1/e_{y'}$, the loop gain for the y' loop becomes from equations 8 and 14

$$A_{y'} = E\cos(\phi-\theta)GH(s) \cong EGH(s) \qquad (16)$$

if it is assumed that the θ loop operates sufficiently well to keep $\phi-\theta$ very small. Note that E, the gradient, is again present in this expression.

The y' loop has now also been reduced to a simple, unity-ratio feedback loop; hence the error in y' position is given by

$$\Delta_{y'}(s) = \frac{y_i'(s)}{1+A_{y'}(s)} \qquad (17)$$

where $y_i'(s)$ is the y' co-ordinate of the desired equipotential line. The exact nature of $y_i'(s)$ and, therefore, the demands made on the system depend on the sweep velocity and on the radius of curvature of the equipotential line to be traced. Let it be supposed that the sweep speed is fixed by specification at some value S_0. Then the expression for $y_i'(s)$ is derived by assuming the y' loop to be inoperative. Under these conditions, reference to Fig. 8 indicates that

$$y_i'(t) = S_0 \int \tan(\phi - \theta)dt$$
$$\cong S_0 \int (\phi - \theta)dt \qquad (18)$$

if $\phi - \theta$ is small. Taking the Laplace transform of both sides results in

$$y_i'(s) = \frac{S_0[\phi(s) - \theta(s)]}{s} \qquad (19)$$

which by use of equation 6 may be written as

$$y_i'(s) = \frac{S_0\phi(s)}{s[1 + KEG_\theta H_\theta(s)]} \qquad (20)$$

Substitution of equations 20 and 16 in equation 17 results in

$$\Delta y'(s) = \frac{S_0\phi(s)}{s[1 + KEG_\theta H_\theta(s)][1 + EGH(s)]} \qquad (21)$$

To illustrate a rough design procedure, all filter and equalizer time constants in $H_\theta(s)$ and $H(s)$ are neglected and only the integration inherent in the drive motors is retained. Thus

$$KG_\theta H_\theta(s) = \frac{K_1}{s}$$
$$GH(s) = \frac{K_2}{s} \qquad (22)$$

Then

$$\Delta y'(s) = \frac{S_0 s\phi(s)}{(s + K_1E)(s + K_2E)}$$
$$= \frac{S_0\phi(s)}{(s + K_1E)(s + K_2E)} \qquad (23)$$

It is seen that the error is directly proportional to the sweep speed S_0 and the rate of change of the slope of the equipotential line ϕ; hence, there is theoretically no error in following a straight line. A more severe test is the tracing of a small circle of radius R, for which ϕ is equal to S_0/R.

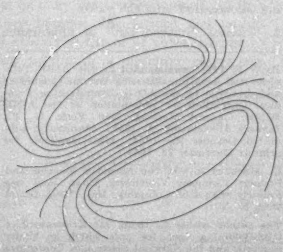


Fig. 9. Field of parallel plane conductors

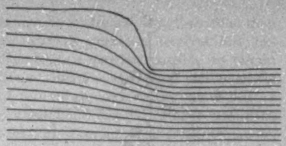

Fig. 10. Field between a plane and stepped conductor

Application of the final value theorem[4] to equation 23 shows that the final error resulting in this test is

$$\Delta y' = \frac{S_0^2}{RK_1K_2E^2} \qquad (24)$$

Thus, a minimum value of $K_1K_2E^2$ is established if specifications of tracing velocity, minimum radius of curvature, and maximum allowable error are given. For the device described here, these specifications were 2 inches per second, $^1/_2$ inch, and 0.1 inch respectively.

Effect of Potential Gradient

The equations indicate clearly the effect of the potential gradient on the accuracy of the system; it is seen that the error is inversely proportional to the square of the gradient. It has also been shown that the loop gains of both the θ and y' loops are directly proportional to the gradient; see equations 5 and 16. Although the simple loop gain functions assumed in equation 22 would represent stable systems no matter what the gain is, in practice the effect of additional time lags in the loops will tend to cause the system to become unstable in regions of large potential gradient. Since the potential gradient in a typical configuration may easily vary over a range of 10 to 1 or more, it is difficult to realize a system combining satisfactory accuracy in regions of low gradient with good stability in high-gradient areas.

One solution is to employ a device to measure the gradient in the neighborhood of the probes, and to use the output of this device to vary the gain of the amplifiers by means of a variable-gain tube. Since loop gain variations of about 2 to 1 can be handled relatively easily with standard equalizer network techniques, this gain compensation need not be very precise. A gradient detector may be realized in the following way: Assume that the θ loop is operating properly and the two probes are aligned on an equipotential line. Let one additional probe be placed at right angles to a line passing through the original two probes so that the three probes form an isosceles right triangle with the main probe at the apex. The voltage between the main probe and the new probe is then a measure of the potential gradient and may be applied to the second grid of the variable μ tube. This technique results in a highly stable system which maintains good accuracy even in regions of relatively low potential gradient.

Recording

The plotting of an equipotential configuration involves not only the tracing of equipotential lines but also the recording of them. The use of the electrolytic tank in this particular system eliminated the possibility of recording directly on the working plane. Thus, voltages proportional to probe position were obtained from 10-turn helipots mechanically coupled to the x and y drive motors. If these voltages are fed to an oscilloscope with d-c amplifiers in the y and x axes, the beam will trace out the equipotentials. An oscilloscope camera with the shutter left open for the duration of the tracing of each equipotential will give a recording of the desired plot.

The voltages could also be fed to an automatic plotting table such as the variplotter. This method was the one used to obtain the three sample plots shown in Figs. 9, 10, and 11. Fig. 9 represents a parallel plane capacitor or a parallel strip transmission line. The field between a plane conductor and a stepped conductor is shown in Fig. 10. Fig. 11 shows the well-known voltage equipotentials for a parallel wire transmission line.

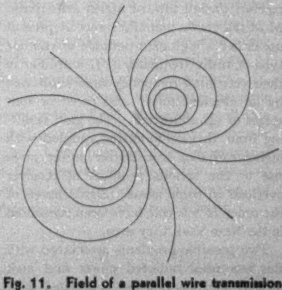

Fig. 11. Field of a parallel wire transmission line

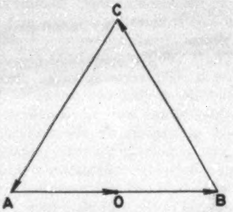

Fig. 12. Space vector diagram of a selsyn output

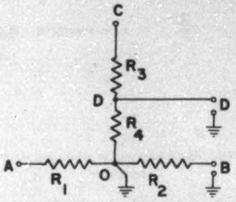

Fig. 13. Resistive network to obtain orthogonal trigonometric functions from a selsyn

Conclusion

The automatic field plotter offers a means of rapid and accurate determination of electric field configurations. Such a device should prove especially useful in situations requiring a large number of successive plots where parameters are varied to obtain an optimum configuration.

Appendix I. The Resolvers

It is well known that, if the rotor of a selsyn (with a nonsalient rotor) is excited with a carrier frequency ω, the amplitude of the carrier voltage between any two terminals will vary sinusoidally with rotor-angular rotation. Thus, the voltage between terminals A and B could be represented by

$$V_{AB}=(GV_R\sin\theta)(\sin\omega t)$$

where θ is angle of rotation, V_R is the peak amplitude of rotor voltage, and G is a constant depending on turns ratio, etc. The other two output voltages attain a maximum amplitude at angles of rotation of 120 degrees more and 120 degrees less than the angle at which V_{AB} is maximum

$$V_{BC}=GV_R\sin(\theta+120^\circ)\sin\omega t$$

and

$$V_{CA}=GV_R\sin(\theta-120^\circ)\sin\omega t$$

Note that the phase of the carrier frequency is the same for all three voltages.

A space vector diagram may be set up to represent the amplitude modulation factors $\sin\theta$, $\sin(\theta+120^\circ)$, and $\sin(\theta-120^\circ)$. This is shown in Fig. 12.

If two equal resistors are connected between points A and B, then the voltages across them are $V_{AO}=V_{OB}={}^1/_2 V_{AB}$. The vector representation of the voltage from their center to point C is seen to be

$$V_{OC}=1.732\,V_{OB}\underline{/+90^\circ}$$

The voltage V_{OC} may be attenuated to equal V_{OB} in magnitude by a resistance attenuator; See Fig. 13.

As long as the total resistance of this attenuator is large compared to the other resistors, no loading will result and V_{AO} will still be in phase with V_{OB}. Thus, the voltage V_{OD} will be 90 degrees out of space phase with V_{OB} and

$$V_{OD}=GV_R\cos\theta\sin\omega t$$

$$V_{OC}=GV_R\sin\theta\sin\omega t$$

It is apparent that the selsyn plus resistive network described are the equivalent of a resolver which produces orthogonal trigonometric functions from an input consisting of angular rotation of the rotor and electric excitation of the stator.

Television Receiver Signal Overload

C. MASUCCI
ASSOCIATE MEMBER AIEE

THE PROBLEM of signal overload has become increasingly severe as a result of the trend in modern television receiver design toward higher sensitivity. Most television manufacturers at present use either a high-gain pentode or cascode type of radio frequency (r-f) amplifier in their very-high-frequency tuners followed by an efficient mixer and three or four stages of amplification. The gain resulting from this combination coupled with higher radiated transmitter power gives rise to the serious problem of receiver overload in some areas. Signal levels of the order of 1.0 volt have been measured in the New York City area.

Two possible problems associated with this increased radiated power and high receiver sensitivities are concerned with the prevention of receiver overload in areas where all signals are high, and the prevention of receiver overload in areas where some signals are high and some are weak.

This latter problem requires for best design and consumer appeal an automatic device which will reduce the receiver's sensitivity or gain for the strong channel and restore it on the weak channel. This paper will discuss this method and also compromise methods for an economy design. The same designs can apply equally well to the first overload condition, i.e., where all signals are of high levels.

Overload Manifestations

Signal overloading in a television receiver manifests itself in numerous ways. A few examples follow.

1. Cross-modulation interference between channels not necessarily adjacent; and between television channels and frequency modulation stations; etc.

2. Noisy pictures in high-signal areas. This is a result of operating r-f and intermediate frequency (i-f) tubes near or beyond cutoff.

3. Sixty-cycle synchronizing buzz especially in intercarrier receivers where the sound is taken from the plate of the video amplifier.

4. Loss of picture synchronization as a result of the compression of the synchronizing information into the video.

5. Picture "washed out" in appearance

Paper 55-139, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 21, 1954; made available for printing December 23, 1954.

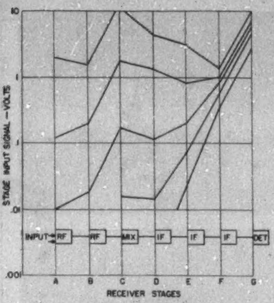

Fig. 1. **Receiver signal distribution for constant antenna input levels**

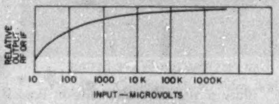

Fig. 2. **Typical stage performance for increasing input signal**

with improper operation of the contrast control.

6. Improper operation of the automatic gain control (AGC) circuit.

7. Complete reversal of picture with, of course, very poor synchronization.

Fig. 1 is a graphic presentation of the signal voltages at various stages for fixed antenna input levels. As can be seen from the signal distribution throughout the receiver, there may be more than one point of overload as the input signal increases. Also, for each individual stage, the signal output (Fig. 2) increases up to a given level and then remains relatively constant for any additional input signal. The point of "flattening" can be called the overload level for each stage.

Another factor of importance to the problem of overload, in addition to the higher gain receivers and higher radiated transmitter power, is that some receivers can be more susceptible to overload than others because of variations, such as cutoff characteristics of i-f tubes, r-f and i-f gain, maximum or minimum power supply voltage available, etc. These variations, of course, are expected and they cannot be controlled any closer than they are without increasing receiver cost, except that it may be possible to obtain closer control of the cutoff characteristic of the tubes used in the controlled i-f stages. Some companies have used tube selection to permit all receivers to handle, at least up to a point, the same signal variations, e.g., 20 to 100,000 microvolts with suitable AGC systems. In addition, tube manufacturers have recently announced the development of tubes with more uniform or remote cutoff characteristics to replace the standard *6CB6* as a controlled i-f stage in a television receiver. They are the miniature types *6CF6* and *6DC6*.

System Considerations

A desirable overload system should supply the necessary attenuation for strong signals in such a manner as to prevent grid rectification in the first r-f stage. The attenuation should be removed when the signal decreases to a predetermined level. It is essential, however, that insertion of attenuation, if automatic, be at a signal level other than that at which it is removed, so that a given signal will not cause the system to "chatter" or "motor-boat."

The possible methods of reducing the probability of receiver overload can be divided into two main groups:

1. Methods of eliminating signal overload in existing television receivers:
   a. Insertion of a resistance attenuator into the antenna lead-in.
   b. Insertion of a resistance attenuator into the r-f tuner section.
   c. Reduction of antenna gain.
   d. Use of quarter-wave stubs.
2. Methods of eliminating signal overload by correctly designed television receiver:
   a. Automatic electronic control: use of a broad-base amplified AGC system.
   b. Automatic electromechanical control: use of a relay to insert a step into the AGC control characteristic.
   c. Manual electromechanical control: use of a switch or potentiometer to insert a step into the AGC control characteristic.

Circuit Considerations

Some of the methods of eliminating signal overload in existing television receivers will be treated first.

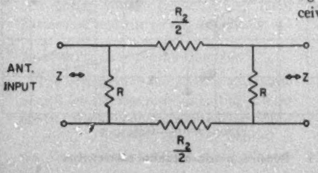

Fig. 3 (left). **A symmetrical π attenuation pad**

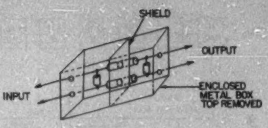

Fig. 4. **Constructional features of the π attenuation pad**

Resistance Attenuation in the Antenna Lead-In

An economical and effective attenuator pad to use is the symmetrical π type shown in Fig. 3.

The unknown values R_1 and R_2 can be determined by the equations

$$R_2 = Z\frac{K^2-1}{2K}$$

$$R_1 = Z\frac{K+1}{K-1}$$

where

Z = antenna and receiver input impedance
K = the voltage or current ratio of attenuation from input to output

Thus for an antenna and receiver input impedance of 300 ohms and a current ratio of attenuation equal to 10 $R_1 = 366$ ohms and $R_2 = 1{,}485$ ohms.

Suitable standard Radio-Electronic-Television Manufacturers Association values for R_1 and $R_{2/2}$ would be 390 and 750 ohms respectively. These choices result in the pad appearing as approximately 325 ohms instead of 300, which is not a sufficient mismatch to the antenna and receiver terminals to cause trouble.

For most effective results the pad should be constructed as sketched in Fig. 4. This method of construction is suggested since the stray signal feedthrough from input to output is reduced to just the distributed capacitance of $R_{2/2}$ which is quite small. The full attenuation for which the pad was designed can therefore be realized. In addition, the pads should be placed as close to the tuner input as practical to eliminate r-f pickup from tuner to antenna input.

This method of preventing receiver signal overload will, of course, result in a reduction of all signals whether strong or weak. Care must therefore be exercised in the amount of attenuation used to prevent unnecessary deterioration of weak signals to favor strong signals.

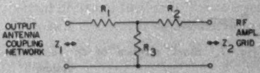

Fig. 5 (right). **An unbalanced T-attenuation pad**

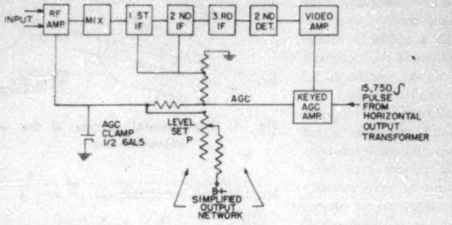

Fig. 6 (left). Block diagram of a keyed AGC type of control system (an automatic electronic control system)

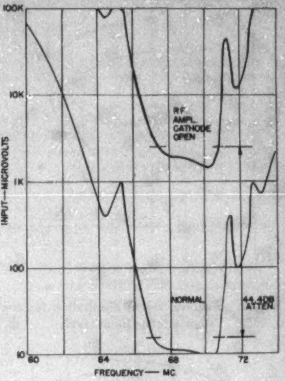

Fig. 8 (right). Comparison of a receiver over-all response with and without overload control

Resistance Attenuation in the R-F Tuner Section

The T attenuator pad shown schematically in Fig. 5 can be used where it is desired to insert attenuation directly into the r-f tuner section. The unknown values R_1, R_2, and R_3 can be determined by using the equations

$$R_1 = Z_1 \frac{(N+1)}{(N-1)} - R_3$$

$$R_2 = Z_2 \frac{(N+1)}{(N-1)} - R_3$$

$$R_3 = 2\, \frac{\sqrt{N Z_1 Z_2}}{N-1}$$

where

Z_1 = output impedance of antenna matching transformer

Z_2 = input impedance of r-f amplifier tube grid

N = power ratio of attenuation from input to output (always greater than unity)

The anticipated attenuation may not be achieved because of the difficulty of shielding input from output when the three resistors have to be inserted on the r-f portion of a turret tuner strip. In fact, it is probable that attenuations greater than 20 decibels may not be feasible. But 20 decibels attenuation will cure many of the overload problems. This method, of course, permits weak signals in the same area on other channels to be received with maximum receiver performance. For the two methods described, there are commercially available economical pads which will give the desired results in most instances.

Reduction of Antenna Gain

The antenna system may have too much gain for the high-signal area in question. A stacked antenna may have been used where only an ordinary dipole with reflector would be sufficient. Of course, the antenna choice must be consistent with good reception on strong and weak signals, if such are available.

If cost is no object, two or more antennas could be used and their gain selected according to the strength of the signal received. The consumer could select the antenna for the particular channel he desires to watch by means of a good quality low-capacity switch. The emphasis on a good switch is necessary so that the intercoupling between antennas is at a minimum. It is also necessary, for low intercoupling, that the lead-ins be spaced as far apart as practical and only come together at the switch. It is also possible by means of commercially available rotatable antennas to reduce the signal input to a receiver, consistent with good reception, and eliminate signal overload.

Use of Quarter-Wave Stubs

Since a resonant transmission line, if opened at one end, presents a short circuit at the first 1/4-wave point, it can be used to act as a short circuit at the picture carrier frequency of the channel being overloaded. A perfect short circuit would attenuate the channel completely. Therefore, the short circuit should be good enough to eliminate signal overload but not entirely lose the picture or sound.

The equation for computing the length of 1/4-wave stub in inches for a 300-ohm twin lead is

$$L = \frac{2{,}425}{f}$$

where f = frequency in megacycles.

A stub for channel 2 which has a video carrier frequency 55.25 megacycles would have a length $L = 2{,}425/55.25$.

This is the value for a theoretically perfect short circuit. The Q of the stub line can be lowered by termination with a

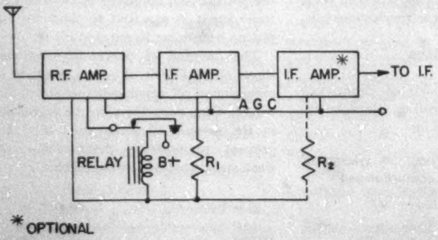

Fig. 7. Block diagram of an automatic electromechanical control system

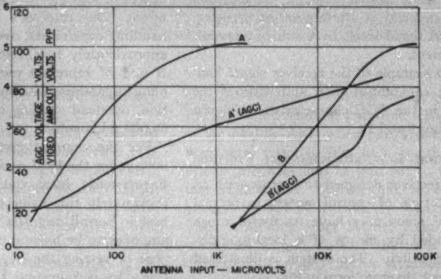

Fig. 12. Comparison of receiver control characteristic and output signal with and without overload

suitable resistance to maintain the correct frequency response within the channel. A method often used in the field consists of shortening the line by cutting 1/8-inch segments until the desired picture attenuation with good sound is attained. Since a stub out for one channel may resonate, e.g. in the 3/4-wave length mode at a higher channel it is necessary that reception on all other channels be carefully checked for picture quality. The stub should not be draped around the antenna lead-in but should for best results be taped to the cabinet if it is of wood. If the cabinet is metal, the stub should be taped to the fiber back of the receiver. Reception of all other channels should be checked to insure good quality.

Methods

The remainder of the paper will discuss methods that can be used in the design of a receiver to permit it to handle signals of high amplitude. In all the methods to be described, the final effect is to insert into the AGC characteristic a step which will permit the receiver to accept larger amplitude signals before the development of negative voltage (AGC action) again flattens off and the receiver overloads.

AUTOMATIC ELECTRONIC CONTROL

The system to be discussed is automatic except for the necessity of setting a level control for best operation in a particular location. However, once the control is set, the operation of the receiver is automatic even though the range of signals available may vary from the very weak to the very strong.

A keyed AGC type of control system, as illustrated in Fig. 6, has inherently a wide range of operation. In particular, the negative voltage developed by such a system is of the order of 10 or more volts. This is a result of: 1. the system operating on sync tips due to the horizontal pulse keying action, and 2. d-c gain.

The system may develop sufficient negative voltage under strong signal conditions to cut off the r-f and i-f tubes. The resultant noisy picture is a by-product of a poor tuner noise factor. To offset this effect, the "level-set" potentiometer *P* as shown in Fig. 6, is adjusted to vary the delay in the action of the AGC on the r-f amplifier during weak signal conditions. The adjustment made for a particular receiver location ensures good reception under strong signal conditions and has little effect on moderate signals.

Since the potentiometer is connected through a large resistor to the power source, it is possible under weak-signal conditions for the effective AGC voltage to be positive. To prevent operating the r-f and i-f tube with a positive voltage on the grids, an AGC clamp 1/2 *6AL5* or equivalent, is used to hold the positive voltage to the minimum, i.e., the drop across a conductive diode. With these refinements, the system can and does perform satisfactorily under most signal conditions.

AUTOMATIC ELECTROMECHANICAL CONTROL

For this method of control, attenuation is inserted into the r-f circuit by means of a relay which is electronically controlled to put a step into the AGC control characteristic of the receiver. Fig. 7 is a block diagram of the method and indicates that it requires the addition of one relay and two resistors (R_1 and R_2) to increase the signal handling capabilities of most present-day receivers.

Essentially, at the time the receiver line switch is thrown, as the receiver warms up, the current flow in the stages will close the relay and it will be held closed by the added r-f amplifier current. As the signal strength increases, the AGC voltage becomes more negative and relay coil current decreases. As the overload point is approached, the decreasing relay current allows the contacts to open the r-f amplifier cathode, thus attenuating the signal and reducing the current flow through the relay coil. The AGC voltage decreases, thereby increasing the current through the i-f stages and relay coil but not sufficiently to close the relay. If the signal decreases further or the receiver is switched to a weaker signal, the decrease in AGC supplies sufficient current to actuate the relay, closing the r-f amplifier cathode circuit and allowing the receiver to operate with normal sensitivity.

The receiver's over-all bandwidth is affected slightly by opening the cathode, as shown in Fig. 8. The attenuation can be varied up to approximately 50 decibels by bridging the r-f amplifier with a suitable *R* or *RC* network. Since this network can remain in the circuit at all times, it has the distinct advantage of requiring no manual switching. The system is sufficiently flexible to permit the insertion and removal of attenuation at predetermined signal levels by a simple relay adjustment.

An example of the receiver signal handling capabilities with and without the step in the AGC characteristic is shown in Figs. 9 and 10.

Manual Electromechanical Control

A receiver designed to operate with an AGC type of control system in normal signal areas may have its useful range extended by means of a local-long-distance switch. The system is illustrated in block diagram form in Fig. 11.

In this method of signal overload control, the AGC voltage is obtained from the second detector and is of necessity a voltage which will vary with the picture content. Also, the maximum negative voltage available for controlling the r-f and i-f tubes is of the order of 5 volts. This is certainly not sufficient to permit control in very strong signal areas.

This system can be aided by the use of a switch which will apply a more negative fixed d-c voltage to the amplifier, in strong signal areas. The result will be that more signal is required to start the average AGC action and therefore the signal-handling ability of the receiver will be extended. This is illustrated in the curves of Fig. 12. Curves *A* and *A'* represent the receiver's normal signal-handling capabilities, overload starting at approximately 1,500 microvolts. Curves *B* and *B'* represent receiver signal-handling capabilities with switch in local position, overload starting at approximately 50,000 microvolts.

For the example given, the negative voltage for the local position was 9 volts. Experiments have indicated that approximately this value of voltage is the best to permit any *3BC5* used as the r-f amplifier to be beyond cutoff. The purpose of setting the negative voltage at this value is to increase the probability of the local-position performance to be acceptable in many receivers and locations.

This method of control can be improved by the addition of a level setter, that is, a potentiometer to vary the negative voltage applied when the switch is in the local position. This will permit the receiver to accept even stronger signals than those indicated in Fig. 12, while maintaining an acceptable over-all noise factor. The tuner noise factor can be further improved by an additional switch section which will reduce the mixer gain along with the r-f amplifier gain when the receiver is operating in the local position. The third position of the local-normal-long-distance switch is useful to obtain the maximum possible receiver gain to permit acceptable fringe area reception.

The methods described and illustrated have all been used with satisfactory results, either alone or in combination. The method or methods used for a particular case will depend on the severity of the problem and whether or not cost is an important factor.

NONMEMBER AIEE

SCIENCE may be defined as "systematized knowledge." Statistics has been called "the technology of the scientific method."[1] Engineering is "the useful application of the findings of science." At first glance, it would appear that these three fields are bound together in an inseparable relationship; but we know that they have always been treated as quite separate areas of interest, both on the campus and in industrial application, and therein lies a problem. While in certain types of engineering the theories of science may be applied without very much knowledge of how these theories were derived, there are other fields of engineering that must use the method of science itself. Reliability engineering is an example. It has arisen with the multiplying complexity and importance of electronic products, and must cope with all of the phases in the evolution of a product, from the designer to the user, and back to the designer. The recent rise of such fields as systems engineering, operations research, and cybernetics seems to have been motivated by this same increasing complexity. Engineers at present are faced with problems of a more and more confusing nature, the solutions for which lie in a more and more theoretical realm. We believe that the traditional, scholastic separation of science, statistics, and engineering creates a problem that is present in all technology, and that while it seriously affects only a few branches of engineering at present, its impact upon all of engineering is both inevitable and imminent.

In the domain of reliability, the problem may be stated as follows: reliability engineering requires the use of the scientific method and (thus) statistics, but today's engineering graduate simply does not have sufficient training in these fields. The purpose of this paper is to show the intimate connection between science, statistics, and reliability engineering, and thereby to demonstrate the need for training engineers more thoroughly in the scientific method.

The Scientific Method

The purpose of science is the understanding of reality, and science has arisen historically from the human need to ad-

---

Paper 55-151, recommended by the AIEE Electronics Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing November 30, 1954.

Fig. 2 (right). The scientific method

just to this reality in order to survive and prosper. The scientific method is the process whereby we reach this understanding of reality, or, in short, it is the way science works, it is what scientists do. We must agree at the onset that this "reality" we speak of is not restricted to past events and that, in fact, the key to the problem of survival lies in our being able to predict the future with some measure of certainty. To help predict future events is the whole aim of science.[2] The only basis for a prediction is observation of past events; and since false or inaccurate predictions are harmful, predictions must be verified so that subsequent predictions will be more certain. From a preliminary standpoint, then, the three basic steps of the scientific method are: 1. Observation. 2. Prediction. 3. Verification.

Predictions have survival value only when expressed in terms of real events. Science is derived from facts and returns to facts for verification; also, since the human brain has but a finite number of brain cells in which it can retain information, it is imperative that all predictions be formulated in the simplest and most general terms possible. But before descending any farther into the details of the scientific method, we must first agree on the meanings of certain words.

The word "fact" is defined as "an event in reality." We shall assume reality to exist in a time-continuum so that events may be assumed predictable as well as observable. When we observe a fact we label it a "phenomenon"; and when we decide to use a phenomenon as a basis for formal thinking, we call it a "datum" or, in the plural ,"data."

The word "hypothesis" is defined as "a tentative proposition based upon facts." Notice that here we do not allow the word hypothesis to take on the meaning of an "a priori" or "self-evident" premise, for science concerns itself only with measurable reality. In other words, imaginary hypotheses are discounted.

The word "inference" shall be defined as "the logical process of forming a conclusion from given data or hypotheses." Inferences are therefore of two kinds: 1. inductive, where one starts with data, and 2. deductive, where one starts with hypotheses.[3] (It is more common to speak of deductions starting from premises than from hypotheses, but we prefer not to use the word "premise" because it carries the connotation of arbitrariness.)

Now consider the concept of "order" (as opposed to disorder or chaos). All our observations show us that no two events are exactly identical, i.e., that every "particular" event is unique. But we also find that several of these particular events may have some characteristics in common, so we group events into classes and then speak of the "general" characteristics of the whole class.

Using these definitions, we can now diagram the two thought-processes of the scientific method, induction and deduction (see Fig. 1). It may help to think of both types of inference as pyramids, with foundations imbedded in particulars and with summits in a cloud of generalities. Induction proceeds upward from the particular to the general, and since generalities are (like clouds) always somewhat hazy and approximate by nature, induction itself is an uncertain process that implicitly involves a statement of probability. Deductions, on the other hand, proceed from the general down to particulars, following established rules of logic. Deduction, therefore, is a "certain" process in the sense that the conclusions follow necessarily from the hypothesis (although not in the sense that the conclusions are certain to be true or certain to be verified).

The scientific method depends equally upon both of these processes of reasoning. It had its historical beginning in induction, which is to say, it sprang from the primitive, animal need for prediction. But induction suffered a terrible setback in the Middle Ages when man's conclusions were given to him as a priori religious principles and he was put to torture for deviation. During that era, man amused himself with deductive exercises (often reasoning from absurd premises, it may be added), so that the rules for deduction developed far in advance of those for induction.[4] In fact, it is still impossible today to delineate complete step-by-step techniques for proceeding from the particular to the general. Modern statistical theory is currently leading the way in the development of these procedures for inductive inference.[5]

It is fundamental that while science periodically soars off in inductive ascensions, it must always return to reality for verification. This process of verification is recognizable to the engineer as nothing more than a "factual feed-back loop." So now, having taken notice of the circularity of science, we can attempt a definition of its method: the scientific method is a self-correcting process of inquiry based upon fact and aimed at verifiable prediction. We can diagram this statement by tying together the two pyramids of induction and deduction as shown in Fig. 2. At the top, we put the "prediction" that is required to shape the conclusion of the inductive inference into a working hypothesis; and at the bottom, we use experimental "verification" to tie the deductive consequences of a hypothesis to the factual foundation of a new induction. It would be misleading, however, to give the impression that a scientific theory is evolved by a single induction and is established by a single deduction. Rather, these two modes of thinking accompany each other in the process; the diagram shows only the very general steps.[6] Deduction comes fairly naturally to us, while induction seems difficult; indeed, it is still quite common to think of scientific induction as being restricted

ol. 74
. 1
955

to the minds of geniuses. However, today it appears that rules for induction are developing and will continue to develop, and that the inductive process may some day become a simple staircase of well-directed deductions. But disregarding these abstractions for a moment, the first step in reaching the goal of prediction is realizing that prediction is the goal.

As to the concept of verification, although it is obviously very important to science that all hypotheses be tested by experimental measurement, it was not until quite recently in man's history that this became part of the scientific method. In 1591, Galileo climbed the Leaning Tower of Pisa and dropped a 10-pound weight and a 1-pound weight together from the top. When it was observed that they struck the ground simultaneously, we say that modern science began.[4] Galileo had returned to the facts for verification of his hypothesis and had thus closed the loop. This act served to warn all scientists not to propose unverified hypotheses, and thus rose the need for objectivity and skepticism, ingredients that have become fundamental to the pursuit of science. As Darwin said, "I have steadily endeavored to keep my mind free so as to give up any hypothesis, however much beloved (and I cannot resist forming one on every subject), as soon as the facts are shown to be opposed to it."[4]

The Role of Statistics

We have already defined statistics as the technology of the scientific method. While probability theory dates back to the 17th Century, statistics is a relatively new field and is still rapidly developing. For this reason, there is considerable disagreement among statisticians as to just what the function of statistics should be.[1,2,5] There seems to be agreement, however, that the mathematical "models" supplied by probability theory are derived deductively from postulates of greater generality, while the statistics that we try to fit to these models are derived inductively from data of less generality. We shall not argue the finer philosophic points here, but merely show where and how statistics fit into the scientific method as currently used in reliability engineering.

Consider again the process of induction (Fig. 1). Induction implicitly involves a statement of probability and thereby indicates (as mentioned before) that statistics is employed. Induction starts from data, and statistics supplies the techniques for marshalling these data. The whole mechanism of statistical synthesis is directed toward describing masses of data with the fewest possible number of characteristics, or "statistics," in other words, toward producing order out of chaos. When we wish to employ statistics to estimate the characteristics of data that we have not yet seen, it can often give us a probability of being correct in our estimates. So statistics lays the foundation for induction and also helps us to some extent to decide which paths of induction are likely to lead toward successful generalization.

Now, consider the deductive process in Fig. 1. Of course, all the practical applications of science fall into this area of reasoning from the hypothesis or theory down to particular conclusions. (Traditionally, this area includes the field of engineering.) We do not usually need the help of statistics to derive these specific applications, for the well-developed rules of deductive logic will suffice. But whenever we decide to test the validity of a hypothesis, we are obliged to call on statistics, for it is statistics that gives us the design of our critical experiment. This experiment must be very carefully planned so as to eliminate or randomize all the variables not under test. That the hypothesis may be tested in the most efficient and exact manner possible. Thus it is the process of verification that specifically requires statistical design; but since a hypothesis is vitally affected, we would be wise to consult the statistician as to the accuracy of our deductive conclusions as well.

The field of statistics, then, is primarily concerned with the foundations of inductive inference and with experimental verification, and it operates in the lower areas of the structure of pyramids (Fig. 2). These lower areas are concerned with facts or data, and it is in these regions that we should expect to find statistics; after all, the field of statistics has arisen to meet the need for the systematic handling of large bodies of data. In the layman's definition, a statistician "analyzes data and tells us what they mean." It must be emphasized that at present the statistician is limited by his theoretical development to the phases of the scientific method that deal with facts or data. Someone else must formulate the hypotheses; someone else must make the predictions. In reliability studies, this "someone else" is an engineer.

Reliability Engineering

The reliability of an electronic product may be defined as the "probability that the product will give satisfactory performance for a specified period of time when used in the manner and for the purpose intended."[6] This definition will serve to convey the scope of reliability engineering, which originates when a product is conceived, follows it through specification, design, development, manufacture, use, and maintenance, and then returns to the point of origin for the development of a new or improved product. The point to be brought out here, however, is not the magnitude of importance of the field, but that this definition is stated in the form of a prediction. The objective of reliability engineering is to present the design engineer with a systematic method for predicting the degree of satisfactory performance he may expect from his product. Of course, there are many such methods already in use in the form of equipment evaluation programs that freed failure information back to the designer. Certainly this concept is not new, and the problem of improving reliability is one of degree. But the degree is not small; considering the increasing reliance placed on electronic equipments, there appear to be several orders of magnitude of room for improvement. Specifically, we want to provide the designer with not only a method for improving existing products, but also a means for forecasting the reliability of new products and, further, with a measure of the certainty of his prediction.

The reliability engineer is faced with the formidable task of developing these long-range predictions. As has been indicated, his most efficient approach appears to lie in using the scientific method, which has evolved over the years for the exact purpose of developing valid predictions. The steps he should take, already outlined, are summarized as follows:

1. Observation—Gather data which will give a measure of the performance of the product and will relate this performance to the time of its operation, the conditions of its use, and the satisfaction of its users.
2. Prediction—Assemble these data and formulate generalizations in the form of brief and simple hypotheses that describe not only the data gathered but also data not yet gathered.
3. Verification—Reason out the logical consequences that these hypotheses suggest, then test them by controlled experiment.

The reliability engineer who follows these steps may be guaranteed success, at least on a logical basis, but the process is not as simple as that.

The Major Problem

First, the engineer has not, as a rule, been subjected to training in the scientific method or in the special field of statistics. He is therefore inclined to use indiscriminately words such as "significance," "average," "probable," "confidence," "frequency," "normal," "representative," etc. He quite justifiably feels frustrated when the statistician objects to his statement. On the one hand he is being paid to produce results, and on the other hand he is criticized for doing so.

Second, even when the engineer has had formal training in the techniques of science, it does not follow that he possesses the imagination required to climb out of a miscellaneous pile of data and up to a valid generalization. It is not so much that an engineer does not like to generalize as it is that he does not always realize that it is necessary to state his generalizations in such a form that they can be tested and experimentally verified. Then, even while we know that these things must be done, it is sometimes hard to say exactly how to proceed. We can only submit that the engineer can become adept in these matters only through a study of science, its method, and its language. Until the time when university curriculums and on-the-job training have met this need, the statistician-consultant is certain to remain the reliability engineer's closest ally.

Conclusion

This paper has attempted to show the intimate relationship between science, statistics, and reliability engineering, and to point out certain incompatibilities between the engineer's educational background and the complexity of the problems he must solve. It may appear that in discussing only the more theoretical aspects of the problem we have ignored the importance of the practical approach and of practical experience. Certainly this was not intended. Good engineers are those who have learned through experience to apply the scientific method, either knowingly or intuitively.

It is emphasized that reliability is an engineering problem: our predictions must be directed toward the design engineer who will use them, and they must be formulated in engineering terminology. Thus, while the specialist or consultant is most valuable and necessary, in the long run it is the engineer who must carry the load. In some instances, however, progress in the improvement of reliability may have to pause for a moment while the reliability engineer stops to think—about thinking.

A Supplement to the Brune Synthesis

F. M. REZA
NONMEMBER AIEE

ONE OF the most elegant contributions to electric network theory was made by Brune[1] in 1931. On the basis of work by earlier contributors, mainly Foster[2], W. Cauer,[3–5] and Fry.[6] Brune proved a fundamental theorem:

"The driving-point impedance of any network made of passive finite lumped linear elements (resistors, capacitors and inductors) is a positive real function of the complex frequency. Reciprocally, given any such function one could find a network configuration consisting of a finite number of linear passive elements having that function for its driving-point impedance."

For the synthesis of positive real functions (prf), Brune suggested the graph of a grounded ladder that correlates the synthesis problem to the expansion of a prf into a continued fraction. The imposition of a particular graph (which is rather a necessity) frequently caused Brune to have negative inductors in his synthesis procedure. However, he was able to prove that the negative inductors occur in a pattern that is equivalent to employing perfectly coupled coils.

Since, from a practical standpoint, the frequent use of perfectly coupled coils is not desirable, there has always been a great desire to eliminate this element. As a step toward this goal, Bode[7] suggests resistance padding. This simple observation has perhaps a deeper significance, since it may imply that proper usage of extra resistances in synthesis relieves the use of transformers. E. A. Guillemin has used in unpublished material some practical methods for eliminating the transformers in special cases. The first existence proof that a prf could be synthesized without transformers was given by Bott and Duffin,[8] whose paper stimulated considerable interest in network circles for further investigation of the problem. At present, it seems that the general problem of the replacement of the transformer in network synthesis with R, L, and C will be one of the most interesting topics of research in network theory.

The aim of this paper is to present a general discussion of the problem of the transformer in 1-terminal-pair networks. The main results have been outlined elsewhere.[9]

Outline of Positive Real Functions and Brune Synthesis Procedure

PRELIMINARY CONSIDERATIONS

The notion of impedance in electrical engineering is a familiar one. For instance, the impedances of a resistor, a capacitor, and an inductor are known to be respectively R, $(1/j\omega C)$, and $j\omega L$ for an applied voltage of frequency ω. Since actually dealing with complex quantities is involved, a complex variable $s=\sigma+j\omega$ may be conveniently defined as the complex frequency. The use of a complex variable s simplifies the study of the circuit and, when dealing with sinusoidal

F. M. REZA is with the Electrical Engineering Department and the Research Laboratory of Electronics of the Massachusetts Institute of Technology, Cambridge, Mass.

This work was supported in part by the Signal Corps; the Office of Scientific Research and Development Command; and the Office of Naval Research.

The author wishes to thank Professor W. R. LePage of Syracuse University for reading the manuscript, and Professors E. A. Guillemin, R. M. Foster and Dr. O. Brune for their continued interest in this work. The material for the Appendix has appeared in the Transactions of the Institute of Radio Engineers Professional Group on Circuit Theory.[11] See also reference 13.

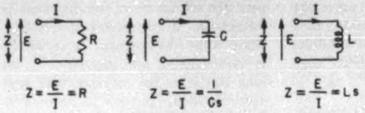

Fig. 1. Driving-point impedances of the three basic linear passive elements

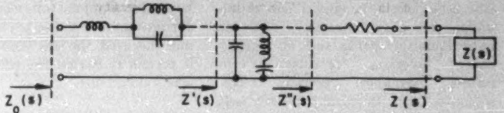

Fig. 3. Reactance, susceptance, and resistance reduction in the Brune synthesis

stimuli, we may finally replace s by $j\omega$. (See Fig. 1.)

Note that the three impedances R, $(1/Cs)$, and Ls are real functions, and their real parts are positive wherever the real part of s is positive

$$ReR = R \text{ essentially positive} \tag{1}$$

$$Re\frac{1}{Cs} = \frac{\sigma}{C(\sigma^2+\omega^2)} > 0 \quad \text{for } \sigma > 0 \tag{2}$$

$$ReLs = L\sigma > 0 \quad \text{for } \sigma > 0 \tag{3}$$

These properties of "realness" and "positiveness of the real part" are two basic properties that characterize all lumped linear passive networks. Indeed, the driving-point impedance $Z(s)$ of a random combination of these elements, as shown in Fig. 2, will preserve these properties. When a current of frequency ω is injected in the network of Fig. 2, the active power delivered to the network will be proportional to the $ReZ(j\omega)$, which must then be a nonnegative quantity.

POSITIVE REAL FUNCTIONS

A rational function $Z(s)$ is said to be a prf if

$Z(s)$ is real for real values of s
$ReZ(s) \geqslant 0 \quad \text{for } Res \geqslant 0$

Theorem 1: If $Z(s)$ is a prf, then $Z(s)$ has no poles in the right half of the s-plane. Poles on the boundary, if any, must be simple and with positive residues.

Since if $Z(s)$ is positive real and consequently $[Z(s)]^{-1}$ is also pr, it can be seen that in theorem 1 the term pole of $Z(s)$ can be interchanged with pole of $[Z(s)]^{-1}$.

Theorem 2: If $Z(s)$ is a prf then the minimum of the harmonic function $ReZ(s)$ in the right half-plane occurs on the axis of imaginaries.

The Schwarz lemma: If $W(\lambda)$ is a function regular in the unit circle $|\lambda| < 1$, and if $|W| < 1$ for $|\lambda| < 1$, and finally $W(0) = 0$, then either

$$|W| < |\lambda| \text{ in the unit circle} \tag{4}$$

or $W(s)$ must be a function of the form $W(s) = Cs$ with $|C| = 1$. Using this fundamental lemma of Schwarz in a polar system, Brune established the following interesting theorem.

Theorem 3: If $Z(s)$ is a prf

for $0 \leqslant |\text{Arg } s| \leqslant \frac{\pi}{2}$

then

$$|\text{Arg } Z(s)| \leqslant |\text{Arg } s| \tag{5}$$

The content of this theorem may be better appreciated in the following form

If $Z(s) = Ls$, where L is a positive constant, then $\text{Arg } Z(s) \equiv \text{Arg } s$. If $Z(s)$ is any other prf, then

$$|\text{Arg } Z(s)| < |\text{Arg } s| \quad \text{for } 0 < |\text{Arg } s| < \pi/2 \tag{6}$$

$$\text{Arg } Z(s) \equiv \text{Arg } s \quad \text{for Arg } s = 0 \tag{7}$$

$$|\text{Arg } Z(s)| \leqslant |\text{Arg } s| \quad \text{for } |\text{Arg } s| = \pi/2 \tag{8}$$

Equations 6, 7, and 8 show that if $Z(s)$ is not of the form $Z(s) = Ls$, then $\text{Arg}|Z(s)| - |\text{Arg } Ls|$ cannot become zero within the right half-plane unless perhaps on the real or imaginary axis. In other words, the function $Z(s) - Ls$ cannot have any zeros within the right half-plane except for the positive real and imaginary axis.

Theorem 4: If $Z(s)$ is a prf and L a positive constant, then $Z(s) - Ls$ (which is not necessarily a positive function) cannot have more than 1 zero within the right half-plane (on the positive real axis).

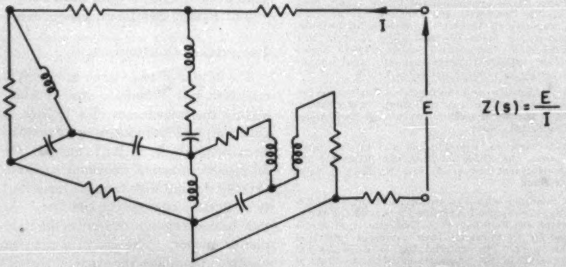

Fig. 2. Driving-point impedance of a general RLC network with mutual coupling

These four theorems, which outline the basic properties of the prf can be found in reference 1 or in texts related to network theory, e.g., reference 10, chapter 6, or reference 4.

BRUNE SYNTHESIS PROCEDURE

Step 1—Reactance Reduction

In conformity with theorem 1, if all j-axis poles of a given prf $Z_0(s)$ are properly removed, the remainder function $Z'(s)$ will be pr. (See Fig. 3.)

$$Z_0(s) = L_\infty s + \sum \frac{A_k s}{s^2+\omega_k^2} + Z'(s) \tag{9}$$

Step 2—Susceptance Reduction

Reconsider step 1 for the function $[Z'(s)]^{-1}$

$$[Z'(s)]^{-1} = C_0 s + \sum \frac{A_k' s}{s^2+\omega_k'^2} + [Z''(s)]^{-1} \tag{10}$$

Repeat steps 1 and 2 until no poles or zeros of the final remainder function $Z''(s)$ lie on the axis of the imaginaries.

Step 3—Resistance Reduction

Study the $Re[Z'''(j\omega)]$ and remove its minimum R in conformity with theorem 2.

$$Z(s) = Z'''(s) - R \tag{11}$$

It is possible that the synthesis of certain prf does not require any other steps. In such cases no mutual couplings are required in the Brune synthesis.

Step 4—Brune Cycle

When confronted with a $Z(s)$ such that the minimum of the $Re[Z(j\omega)]$ is zero and $Z(j\omega_0) = jL_1\omega_0$, remove a series inductance L_1; if L_1 is positive, then $Z(s) - L_1 s$, by virtue of theorem 4, ceases to remain a positive function and will have a positive real zero. Nevertheless, the nonpositive function $Z(s) - L_1 s$, which has a pair of zeros on the axis of imaginaries, suggests the application of step 2, followed by step 1. This final step introduces a negative inductor L_3. Brune proves that even with $L_3 < 0$, L_1, L_2, and L_3 collectively define a perfect transformer since

$$L_1L_2 + L_2L_3 + L_3L_1 = 0 \tag{12}$$

This step is called the Brune cycle (Fig.

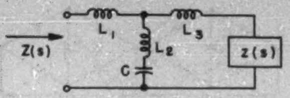

Fig. 4. Brune cycle

4). If $L_1<0$, $Z-L_1s$ will be pr, and steps similar to those given in the foregoing will lead to a Brune cycle, where $L_1<0$, $L_2>0$, $L_3>0$, and equation 12 is also valid; hence a physical realization in the form of a perfect transformer is immediate.

The remainder function $z(s)$ will be synthesized in the same manner. References 1 and 13 present elaborate proof of the positive real character of $z(s)$.

Synthesis Without Ideal Transformers

In the Brune synthesis of a driving-point impedance $Z(s)$, when $ReZ(j\omega)$ has a finite minimum along the axis of imaginaries (real frequencies), one is confronted with closely coupled coils. Let $Z(s)$ be such a function, whose minimum real part has been removed. As a result of the Brune cycle it is known that the removal of elements L_1, L_2, L_3, and c, shown in Fig. 4, will lead to a positive real function $z(s)$ which may or may not contain perfect couplings in its Brune configuration. From Fig. 4 is derived

$$\frac{1}{Z-L_1s}=\frac{cs}{cL_2s^2+1}+\frac{1}{L_3s+z} \tag{13}$$

$$Z_1(s)=Z-L_1s=\frac{(L_3s+z)(cL_2s^2+1)}{[c(L_3+L_2)s^2+1]+csz} \tag{14}$$

From theorem 4 we know that $Z-L_1s$ may have only 1 real zero in the right half-plane. Denoting this zero by k

$$Z(k)-L_1k=0 \tag{15}$$

and from equation 14

$$z(k)+L_3k=0 \tag{16}$$

In an effort to avoid the obstacle of the perfect coupling, it seems natural at first to attempt the Brune synthesis of the reciprocal function on the admittance basis (reference 11, p. 368).

$$Y_2=\frac{1}{Z(s)}-As$$

where A is a positive constant. Since $[Z(s)]^{-1}$ is a prf with $Re[Z(j\omega)]^{-1}=0$ then, from theorem 4, it can be seen that Y_2 has all of its poles and zeros in the left half-plane or the boundary, except for 1 positive real zero (since L_1 is assumed to be positive). A may be selected such that the positive real zeros of Z_1 and Y_2 coincide. Then

$$\frac{1}{Z(k)}-Ak=0,\ A=\frac{1}{L_1k^2} \tag{17}$$

Now, for this value of A, the ratio Z_1/Y_2 will have no poles or zeros within the right half-plane.

$$\frac{Z_1}{Y_2}=\frac{Z-L_1s}{1-AsZ}Z=\frac{Z-L_1s}{L_1k^2-sZ}L_1k^2Z \tag{18}$$

It can be shown that the function

$$Z_3(s)=k\frac{Z-L_1s}{k^2L_1-sZ},\ L_1>0 \tag{19}$$

is a prf. In fact, if $Z(j\omega)=U+jV$, then

$$ReZ_3(j\omega)=k\frac{L_1U(k^2+\omega^2)}{(k^2L_1+\omega V)^2+\omega^2U^2},\ L_1>0 \tag{20}$$

which is evidently positive, for all real finite values of ω. The network configuration of Fig. 5 is an immediate consequence of equations 19 and 20.

$$Z=kL_1\frac{kZ_3+s}{k_1+sZ_3}=\frac{1}{\dfrac{Z_3}{L_1k}+\dfrac{1}{L_1s}}+\frac{1}{\dfrac{s}{L_1k^2}+\dfrac{1}{kL_1Z_3}} \tag{21}$$

Note that Z_3 is not only a realizable function but is also simpler than the original function $Z(s)$. This is because Z_3 has a pair of zeros at $s=\pm j\omega$; hence its synthesis following Brune procedure allows the susceptance reduction (step 2). The continuation of Brune synthesis of function $Z_3(s)$ may be again confronted with perfect transformers. In such case the cyclic procedure described in the foregoing may be continued. This result was first introduced in reference 9.

Conversion Cycle

The next task is to determine the element values of Fig. 5. Since $Z_3(s)$ has a pair of zeros on the axis of imaginaries, step 2 of the Brune synthesis suggests that according to the partial fraction expansion of equation 10, the corresponding residues for these poles of $1/Z_3$ be removed.

$$\text{Residue of }\left(\frac{1}{Z_3}\right)\text{ at }\omega=\frac{\pm j}{(L_2/c)^{1/2}}=\frac{L_1(k^2L_2c+1)}{2kL_2^2c} \tag{22}$$

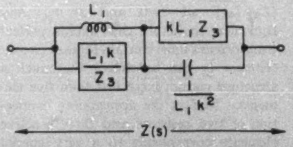

Fig. 5. Equivalent structure for a Brune cycle

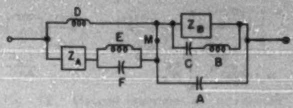

Fig. 6. Balanced bridge conversion cycle for a Brune cycle

Let the corresponding elements be an inductor and a capacitor with respective values L_v and c_v. Then

$$L_v=\frac{L_1(k^2L_2c+1)}{kL_2}$$
$$c_v=\frac{kL_2^2c}{L_1(k^2L_2c+1)} \tag{23}$$

(The reader is assumed to be familiar with the so-called Foster expansions of reactances. See reference 11.) This suggests the equivalent configuration of Fig. 6 for Fig. 5. Equations 23 and 21, along with the configuration of Fig. 6, show that

$$Z_B=\frac{L_1k}{Z_3}-\frac{L_1^2(cL_2k^2+1)s}{L_2(cL_2s^2+1)} \tag{24}$$

$$\frac{1}{Z_A}=\frac{1}{kL_1Z_3}-\frac{(k^2L_2c+1)s}{k^2L_2(cL_2s^2+1)} \tag{25}$$

or, after some algebraic operations, it may be found that

$$Z_B=\left(\frac{-L_1^2}{L_3}\right)\left(\frac{-L_3k^2-sz}{L_3s+z}\right) \tag{26}$$

$$Z_A=\left(-k^2L_3\right)\left(\frac{L_3s+z}{-sz-L_3k^2}\right) \tag{27}$$

Since $L_1>0$, $L_3<0$ has been considered, it can be seen from equations 19 and 20 and theorem 4 that Z_A and Z_B are prf, in spite of some negative values appearing in equations 26 and 27. Note that according to equation 16 the number k is the common zero of $L_3s+z(s)$ and L_3k^2+sz. If in the Brune cycle $L_3>0$, $L_1<0$, similar treatment of the problem on the admittance basis can be given.

From this discussion it is concluded that the structure of Fig. 6 should be considered a conversion of the Brune cycle. Indeed, each element A, B, C, D, E, F, Z_A, and Z_B of Fig. 6 is an explicit function of the elements appearing in the Brune cycle of Fig. 4. Hence the following steps are suggested as supplements to the Brune procedure.

SUPPLEMENT TO BRUNE PROCEDURE

Step 5—Element Values

When the first Brune cycle with ideal transformer is determined, then draw the conversion cycle (Fig. 6) and find its element values from equation 28.

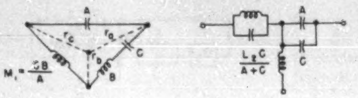

Fig. 7. A Δ-Y transformation applied to the balanced bridge conversion cycle

$$A=\frac{1}{L_1k^2} \qquad D=L_1$$

$$B=\frac{k^2L_2^2c}{k^2L_2c+1} \qquad E=\frac{L_1^2(k^2L_2c+1)}{L_2}$$

$$C=\frac{k^2L_2c+1}{k^2L_2} \qquad F=\frac{L_2^2c}{L_1^2(k^2L_2c+1)} \tag{28}$$

$$Z_A=k^2L_3\frac{L_3s+z}{sz+L_3k^2} \qquad Z_B=\frac{L_1^2}{L_3}\frac{L_3k^2+sz}{L_3s+z}$$

(For $L_1 < 0$, proceed on the admittance basis.)

Step 6—Continuation

Continue with the Brune synthesis of Z_A or Z_B. (Z_A is the reciprocal of Z_B within a constant multiplier.)

A Bridge Conversion Cycle

In this section will be described a conversion cycle with fewer elements than the cycle described in the preceding section. Two methods of solution will be discussed, one as an improvement of the previous cycle, the other as a rather independent solution that may have other possibilities.

METHOD A

The conversion cycle described in the previous section possesses the structure of a balanced bridge

$$L_1s\times\frac{L_1k^2}{s}=kL_1Z_3\times\frac{kL_1}{Z_3}=k^2L_1^2 \tag{29}$$

Hence the opening of the node M in Fig. 6, or the insertion of any passive impedance in that branch, will not affect the balance of the bridge; and inserting an inductor may be considered, with inductance $M_1=CB/A$ of such a form that the four elements (B, C, M, and A) also form a balanced bridge. Now we may apply a Δ-Y transformation as shown in Fig. 7. After some algebraic manipulations, the following results are obtained

$$r_a=\frac{1}{(A+C)s}$$

$$r_b=\frac{L_2cs}{A+C} \tag{30}$$

$$r_c=\frac{C\times L_2cs}{A(A+C)(L_2cs^2+1)}$$

Now r_c and the parallel resonant circuit of E and F could be combined to give a new parallel resonant circuit.

$$r_c+\frac{Es}{EFs^2+1}=\frac{s}{L_2cs^2+1}\left(\frac{CL_2c}{A(A+C)}+E\right) \tag{31}$$

This leads to the unbalanced bridge conversion cycle of Fig. 8 and equation 32.

$$D=L_1s$$

$$M=\frac{L_2L_3ck^2}{L_3ck^2-1} \qquad N=\frac{L_2c}{M}=c-\frac{1}{k^2L_3}$$

$$E_1=\frac{L_1^2(1+cL_3k^2)^2}{L_2(1-cL_3k^2)} \quad F_1=\frac{L_2^2c(1-cL_3k^2)}{L_1^2(1+cL_2k^2)^2} \tag{32}$$

$$Z_A=\frac{k^2L_3(L_3s+z)}{sz+L_3k^2} \quad Z_B=\frac{L_1^2k^2}{Z_A}$$

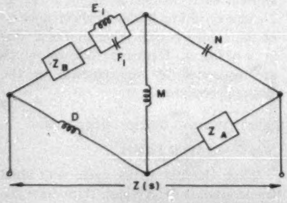

Fig. 8. An unbalanced bridge conversion cycle

Note that all elements appearing in Fig. 8 are physically realizable without the use of perfect transformers.

METHOD B

The search for a conversion cycle may be begun by considering a biquadratic driving-point impedance function presenting one Brune cycle such as that shown in Fig. 4, with $z(s)=r$. Then

$$Z(s)=\frac{[(L_1+L_2)cs^2+1]r+(L_1+L_3)s}{[(L_2+L_3)cs^2+1]+rcs} \tag{33}$$

The Brune cycle representing equation 33 uses one resistor, three positive reactive elements, and one negative inductor. The existence of the perfect coupling ($L_1L_2+L_2L_3+L_3L_1=0$) allows the use of only one resistor r in a network which must behave, respectively, as r and $[(L_1+L_3)/(L_2+L_3)]r$ at $s=0$ and $s=\infty$. Any equivalent structure that avoids perfect transformers must contain at least two resistors. It can be shown that such a structure cannot have less than five elements. In fact the appropriate connection of two resistors and three reactive elements corresponds to a very special subclass of the general biquadratic $Z(s)$.

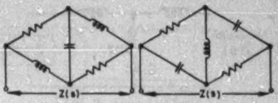

Fig. 9. A particular bridge for presenting a subclass of biquadratic positive real functions

Fig. 9 shows such configurations, but they do not cover the general problem. But there was in the preceding section a conversion cycle for the general biquadratic $Z(s)$ containing eight elements. This suggests a search for a structure containing two or three resistors and four or five positive reactive elements. The detailed solution to such a problem is not given here although it seems worthy of discussion. When some familiarity with the problem is established, it is rather natural to consider a structure similar to that shown in Fig. 10. In fact, if $Z(j\omega_0)=jL_1\omega_0$, then at $s=j\omega_0$ the two resistors must be deprived of dissipation. In the light of the next section two resonant and antiresonant tanks are first considered. The structure of Fig. 10 suggests itself as a possible solution.

The values of $Z(0)$ and $Z(\infty)$ determine the magnitude of the two resistances. Also, it is evident that for Fig. 10 to be the equivalent of Fig. 4 (for $z=r$) it must necessarily be assumed that

$$E_1F_1=L_2c \quad M_1N=L_2c \quad D=L_1 \tag{34}$$

The driving-point impedance pertaining to the bridge of Fig. 10 is a rational function $Z(s)=[N(s)/D(s)]$, where $D(s)$ and $N(s)$ are, in general, 5th-degree polynomials.

$$\begin{aligned}N(s)=(L_2c)^2aL_1rs^5&+[(M_1+E_1)L_1L_2c+\\ ar^2L_2c(L_2c+L_1N)]s^4&+[(M_1+E_1+\\ L_1)L_2cr+2L_1L_2car&+ENrL_1]s^3+\\ [(M_1+E_1)L_1+ar^2L_2car^2L_1N]s^2&+\\ [(M_1+E_1+L_1)r+arL_1]s&+ar^2\end{aligned} \tag{35}$$

$$\begin{aligned}D(s)=L_1(L_2c)^2s^5&+[(L_2c)^2r(a+1)+\\ L_1L_2crN]s^4&+[(M_1+E_1)L_2c+\\ 2L_1L_2c+ar^2L_2cN]s^3&+[L_2cr(2a+\\ 1)+rN(E_1+L_1)]s^2&+[(E_1+L_1+\\ M_1)+ar^2N]s&+ar\end{aligned} \tag{36}$$

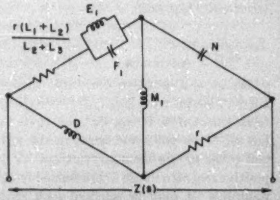

Fig. 10. Bridge conversion cycle for biquadratic case

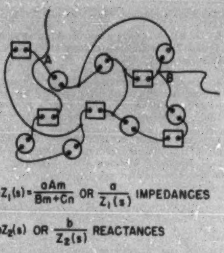

A
B
$aZ_1(s)=\frac{aAm}{Bm+Cn}$ OR $\frac{a}{Z_1(s)}$ IMPEDANCES
$bZ_2(s)$ OR $\frac{b}{Z_2(s)}$ REACTANCES

Fig. 11. General configuration made by random combination of two particular classes of prf's generating mutual coupling in the equivalent Brune configuration

where

$$a=\frac{L_1+L_3}{L_2+L_3} \tag{37}$$

Conditions for the identity of equation 29 with $[N(s)/D(s)]$ could be obtained in a straightforward but rather tedious computation. These conditions are found to be

$$D=L_1,\ M_1=c-\frac{L_3}{r^2},\ E_1=\frac{L_1^2(1+cL_3k^2)^2}{L_2(1-cL_3k^2)} \tag{38}$$

These considerations provide a bridge conversion cycle for converting a Brune cycle with perfect couplings into a cycle without couplings and containing fewer elements than the previous conversion cycle. To justify this general statement we can replace the resistor r in Fig. 4 by the function $z(s)$, which is the remainder of the Brune cycle. In Fig. 8, r and ar will be replaced, respectively, by Z_A and Z_B as found in the preceding section. It is a matter of algebra to check the fact that the identity of the two configurations is not altered by these operations. Thus one obtains results identical to that of method A. (The writer has established this identity algebraically but will omit that process for the sake of briefness.)

As an alternative to step 5, the following is offered as step 5(A): When the first Brune cycle with perfect couplings is determined, draw a bridge conversion cycle (Fig. 8) and find its elements from equation 32. (For $L_1<0$, proceed on the admittance basis.)

Concluding Remarks

The present trend of thought in the theory of communication engineering indicates that the different aspects of the problem of the synthesis of electrical networks will for some time be an important topic of theoretical and practical significance. A great variety of problems in other fields could be translated in terms of combination of linear network elements; analytical experience gained in the synthesis of networks is often useful in the design of other systems.

The problem of network synthesis is actually the problem of expanding a function into linear components with certain restrictions. Among the basic expansion methods, the expansion in continued fractions has an outstanding position. Since the Brune synthesis of a driving-point impedance consists of its continued fraction expansion, there is no doubt that its significance is not casual.

It is hoped that the present work will be of interest to those using the Brune synthesis, inasmuch as it offers a unified synthesis procedure using positive elements only. There are many other important related questions that remain unsolved. For instance, it was mentioned that if $Z(s)$ is a biquadratic prf, the Brune configuration of which presents a perfect coupling, an equivalent structure without couplings could be found with not more than seven elements. However, when $Z(s)$ requires n perfect couplings for its Brune configuration, the minimum number of elements for the equivalent structure without perfect couplings is not yet known.

Appendix. Generation of Driving-Point Impedance Functions Leading to Mutual Coupling[12, 13]

In the strictest interpretation of the Brune synthesis, the poles and zeros of the impedance function on the imaginary axis are first removed until the remainder function no longer has any more of them. Next, the smallest value of the real part of this impedance function for real frequencies must be removed. If the numerator of the $Re[Z(j\omega)]$ of the remainder has one or more roots at a finite nonzero real frequency, then the Brune synthesis requires mutual coupling. In such cases, the numerator of the $Re[Z(j\omega)]$, as a function of ω^2, will have one or more positive real roots of even multiplicity. In this study, "network with mutual coupling" refers to a driving-point impedance function having the last-mentioned property.

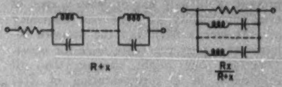

Fig. 12. General structure of a network block which, when embedded in a network, will generate mutual coupling in the equivalent Brune network

To identify the general class of positive real functions with this property, consider first the special class of driving-point impedances

$$Z_1(s)=\frac{Am}{Bm+Cn}=\frac{1}{1/R+1/[F(s)]} \tag{39}$$

where $m(s)$ and $n(s)$ are respectively even and odd parts of any Hurwitz polynomial of a degree higher than 1, and A, B, and C are positive real constants. $Z_1(s)$ can be synthesized immediately in the form of a resistance $R=A/B$ in parallel with a reactance $F(s)=Am/Cn$. Now consider the arbitrary reactance function $Z_2(s)$ and its inverse function $1/[Z_2(s)]$ combined with $Z_1(s)$ and $1/[Z_1(s)]$ in a random manner, as illustrated in Fig. 11.

$$Z(s)=\psi(Z_1, Z_2) \tag{40}$$

It is now possible to prove that the combination of these two classes of functions generates a network with mutual couplings. In fact, if $Z(s)$ is the driving-point impedance between any two nontrivial nodes A and B it has only to be proved that $Re[Z(j\omega)]$ has some positive ω^2 zeros of even multiplicity.

The $Re[Z_1(j\omega)]$ vanishes at the real frequencies $\omega_1, \omega_2, \ldots, \omega_n$ which are roots of $m(s)=0$. Assume a voltage of frequency ω_1 applied to the terminals A and B. Since $Z_2(s)$ is lossless, and the cubic blocks of Fig. 11 at such a frequency are either short-circuited or open-circuited, there must be no power dissipation. This means that ω_1^2 is a root of even multiplicity for $Re[Z(j\omega)]$. The original characteristic of the network $Z_1(s)$ is thus preserved through its block combination with lossless networks.

If $Z(s)=(m_1+n_1)/(m_2+n_2)$ is a prf representing mutual coupling in the Brune

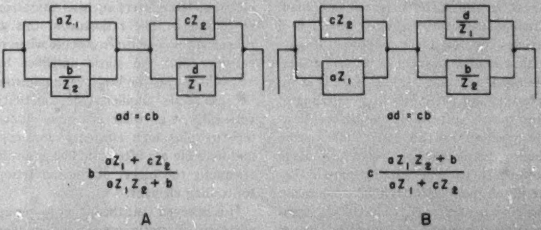

Fig. 13. A basic structure that presents mutual coupling in its Brune equivalent presentation

process, $Re[Z(j\omega)]$ has at least a root of even multiplicity at some real frequency ω_1. At such a frequency the network behaves as a pure reactance m_1/n_2 or n_1/m_2. Therefore, one might suppose that all resistances in a representation of $Z(s)$ which avoids mutual couplings would appear either in series with a parallel resonant circuit of frequency ω_1, or bridged across a series-resonant circuit of the same frequency. Thus, in general, it might be expected that these resistances would occur as a part of network blocks of special form, as shown in Fig. 12.

$$Z_1(s)=R+x \text{ or } Z_1(s)=\frac{Rx}{R+x} \tag{41}$$

The size of R and the impedance levels may vary for different blocks but the configurations are of the same general structure.

It is interesting to note that the parallel combination of $Z_1(s)$ with a reactance, as well as the series combination of $1/[Z_1(s)]$ with reactances, is generally recognizable in the Brune process without mutual coupling. The removal of poles and zeros of $Z(s)$ on the imaginary axis reveals such configurations except in particular cases of such mixed combinations as are shown in Fig. 13. These are among the general structures which cannot be broken down without mutual coupling in the Brune process. Without loss of generality let $Z(s)=s$; thus in Fig. 13 is recognized the structure used in the Bott and Duffin procedure.[8]

In the discussion of the converse property it has been assumed that the network is composed essentially of a combination of two kinds of functions: $Z_1(s)$ and reactances. For the more general case the possibility is readily conceivable of having other networks immediately in series or parallel with $Z_1(s)$. The general pattern of the somewhat "localized resistances" will still be retained.

For obvious reasons the function $Z_1(s)=1/[1+F(s)]$ might be called the generating function for the class of RLC impedances the Brune configuration of which represents mutual coupling.

It is important to note that in the synthesis of the impedance functions the freedom of choosing different graphs is possible. An impedance function requiring mutual coupling in a ladder structure may not necessarily require such coupling in a lattice structure.

In a more general attempt to find configurations avoiding mutual couplings, topological graphs are conceivable other than those of Figs. 12 and 13 for representation of driving-point impedance functions. In fact, if G is such a configuration, the resistances in G must be deprived of the flow of the current at applied voltages with those real frequencies which will make $Re[Z(j\omega)]$ minimum (except $\omega=0$ and $\omega=\infty$). Putting the case of Fig. 12 aside, other suitable graphs may be found by imposing the restrictions that at certain given applied frequencies, and only at those frequencies, the node voltage distribution in the graph must be such that any node pairs at terminals of a resistance will be equipotentials.

160,000-Ampere High-Speed Magnetic-Amplifier Design

ALLEN B. ROSENSTEIN
ASSOCIATE MEMBER AIEE

THE PAST 8 years, with the advent of improved semiconductor rectifiers and the availability of high quality magnetic materials have seen greatly renewed interest in the static magnetic amplifier. Current literature offers a number of articles on magnetic-amplifier theory, with a smaller number of reports available on design and application. It is interesting and perhaps a little puzzling to note that in spite of the fact that saturable reactors in the early 1900's were chiefly employed as relatively large power regulating devices, the present-day trend of magnetic-amplifier application has been toward small to moderate signal and power control. The controlled power design tendency has been to use low-level static magnetic amplifiers driving higher power rotating magnetic amplifiers such as rotatrols, amplydynes, and conventional generators or controlling electronic converters such as thyratrons or ignitions. The rationale of this arrangement is sometimes obscure when we consider that the static amplifier has been chosen for the low-level application because of its simplicity, dependability, versatility, etc., while the same characteristics plus high efficiency, low cost, and long life are often overlooked in determining the higher power converting-controlling element.

It is believed that the higher power application of static magnetic amplifiers may be limited, in part because of engineering concepts of magnetic-amplifier size, weight, power amplification, and speed of response that have carried over from the early saturable reactor days. It is not generally recognized, for example, that a static magnetic-amplifier regulated rectifier can inherently be made smaller and lighter than a comparable motor generator set or that the magnetic amplifier is capable of meeting and exceeding most of the performance characteristics of thyratrons and ignitions including that of half-cycle response. As a small effort to extend our static magnetic-amplifier power horizons, this paper will describe a high-power, fast-response magnetic amplifier which the author designed in 1950 and which has seen several years of highly successful service. An idea of the size of this magnetic amplifier may be

Y., January 31–February 4, 1955. Manuscript submitted October 4, 1954; made available for printing December 9, 1954.

A. B. ROSENSTEIN is with the University of California, Los Angeles, Calif., and consultant to Inet, Los Angeles, Calif.

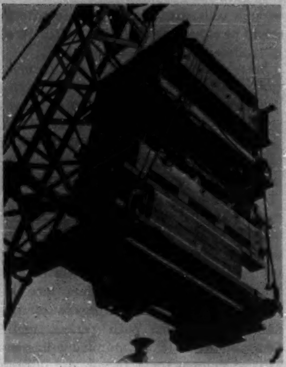

Fig. 1. Assembled unit hoisted for entanking

had from the fact that it contained over 20,000 pounds of copper, was capable of supplying up to 160,000 amperes (amp) of direct current and yet was controlled by 500 milliamperes (ma) of current. Figs. 1 and 2 give internal and assembled views of the amplifier. The over-all weight of the amplifier and accessories was 154,280 pounds. Exclusive of the transformer copper, 11,010 pounds of bus bars were used. The saturable reactor cores utilized over 4 tons of grain-oriented steel. The four steel containers each measured 11 feet high by 7 feet 4 inches by 5 feet 8 inches wide. Eight thousand gallons of oil were required to fill the system. The machine was the result of a complete survey of existing electric equipment to meet the specifications in Table I.

Equipment to meet the specifications were analyzed from the standpoint of efficiency, dependability, flexibility (it was desirable but not necessary to obtain higher voltages at reduced currents), and optimum approximation of the desired specification. Machinery considered included ignitrons, homopolar generators, d-c generators, and low-frequency alternators. The d-c magnetic amplifier was selected as being capable of most nearly approaching ideal performance.

General Considerations in Amplifier Design

Direct current was chosen to eliminate the high-current reactive drop of the load loop. However, inductive phase voltage drops are of prime concern in any low-voltage, high-current magnetic amplifier or rectifier. The effects of inductance will be discussed in detail in the section "Electrical Design." Here it can be seen that the inductive voltage loss renders a single unit construction impractical for 160,000 amp. This plus the need for transportability, and the additional flexibility, available from series-parallel connections, led to a decision to construct the amplifier in four equal sections, each rated 30,000 amp continuous. By changing the external bussing, four units allow adjustable voltage ranges of 8 to 56 volts, 4 to 28 volts and 2 to 14 volts. Fig. 3 gives the elementary block diagram for one unit.

Inductive voltage drops were further minimized through the use of the 3-phase, double half-wave circuit with interphase transformer. Each half-wave section then had to supply one half of the total current rating of the unit. The 3-phase, half-wave circuit offers maximum selenium cell economy and maximum over-all electrical efficiency for low-voltage operation. Double half-wave rectification gave improved transformer utilization, reduced telephone interference in the high-voltage supply, and allowed a conveniently balanced mechanical design.

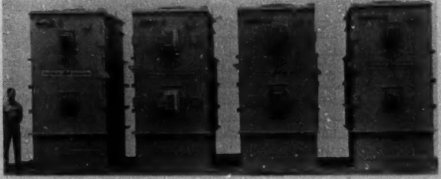
REACTORS

Table I. Specifications for Magnetic Amplifier

Input: 12,800 Volts, 3 Phases, 60 Cycles. Output Range: 2 to 14 Volts at 15,000 to 160,000 Amp. Control Adjustment Continuous from 2 to 14 Volts

Maximum Ratings	Volts	Amp	Output, Kw	Time Duration Seconds,
Continuous	14	120,000	1,680	
Intermittent	14	160,000	2,580	
Response time	1$^{1}/_{2}$ to 3 cycles			
Double-power cycle (to be repeated indefinitely)	7.5 10.6	119,000 168,000	890 1,780	9 1

Output control was achieved through the use of six self-saturating reactors per unit. These reactors (see Figs. 3 and 4) were located in the transformer secondary circuit with each reactor connected in series with one phase of the selenium rectifier to form a polyphase self-saturating d-c magnetic amplifier. The electromechanical characteristics of the chosen magnetic-amplifier circuit had to be balanced against those of the self-saturating magnetic amplifier connected in series with the transformer primary. For most high-current applications the mechanical problem attendant to feeding the heavy current through the reactors in the secondary circuit causes the primary doubler circuit to become mechanically attractive. In this particular case a unique electromechanical construction was evolved which caused the secondary reactor to be mechanically sound. The secondary magnetic amplifier introduces a voltage drop into the secondary circuit which necessitates a larger transformer than is required with a primary doubler. This transformer cost can be balanced against the additional selenium rectifiers required for the doubler circuit and the high-voltage insulation required in the power winding of the primary doubler. An



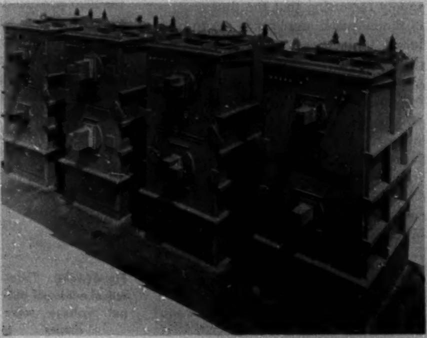


Fig. 2. Amplifier views from output side

additional important factor to be considered with the primary doubler is the d-c component of current which would flow in the transformer primary should there be any unbalance between the reactors of the doubler. The possibility of this direct current necessitates a slightly more liberal transformer steel allowance. The doubler also has a slower inherent speed of response. After carefully weighing the advantages of both reactor locations, it was decided that the integral mechanical construction offered by the secondary reactors overweighed any possible disadvantages.

Some of the mechanical problems of the reactors have been mentioned. Reactor space restrictions were also rather severe. Because of the extreme voltage range of the equipment, the reactors had to be large enough to absorb practically all of the transformer secondary voltage. Each reactor set had to be wound with copper capable of carrying up to 20,000 amp. The transformer secondary voltage and the inverse rating of the rectifier cells were directly dependent upon the degree of saturation that the control current could effect in the reactors. Therefore, residual reactance of the reactors had to be reducible at full ouput to a relatively small value.

The extremely fast response required for the double power cycle dictated that the magnetic-amplifier power gain be something less than 10,000/1. At the same time, the control of the double power cycle was expected to be very precise and completely dependable. By increasing the number of reactor control turns, the control current required by the magnetic amplifier could be reduced to a value that vacuum tubes could readily handle. With increased turns the voltages induced in the control windings increases the insulation problem and increases the required output voltage of the control supply (assuming that the time constant of the magnetic amplifier is not to be allowed to increase). For a given time constant, the reactor control power required becomes independent of the number of reactor control turns. Reactor control windings were selected to require a maximum of 500 ma allowing the use of moderate-sized transmitting tetrodes as control elements.

Although it was expected that a small amount of individual unit gain control would be necessary to final balancing of the units in parallel operation, strict quality control was exercised throughout the manufacture of the equipment to insure reactor balance within and between units over the complete operating range. Reactor cores were pregraded to within ±2½ per cent (%) before installation, and rechecked after installation.

Interphase

The interphase reactor design problem was more mechanical than electrical. Electrically, it was necessary to recognize that the shift in firing angle introduced by the magnetic gates (reactors) would cause a larger 180-cycle voltage to appear across the interphase than simple rectifier theory would predict. Mechanically, the problem was that of building a 30,000-amp interphase into a minimum of space while providing a convenient connection between the double-wye neutrals and the output terminal.

Selenium Cells

Although the selenium rectifier design presented some mechanical problems, they were largely based upon economic considerations. A low inverse voltage rating of the selenium cells would force extremely careful transformer-reactor design in order to allow maximum d-c output with a minimum transformer secondary voltage, but would permit higher efficiencies. High selenium cell inverse voltage ratings are usually accompanied by higher voltage drops in the forward direction and consequently reduced magnetic-amplifier efficiency. Since the magnetic amplifier was entirely self-contained and oil-immersed for outdoor operation, the heat produced by the losses had to be dissipated in a suitable heat exchanger. As sufficient cooling water was not available, oil-to-air heater exchangers were used. The size and cost of these exchangers was, of course, a direct function of the over-all amplifier efficiency. Although cells with higher inverse ratings might have been available, 33-volt inverse cells offered efficiencies of over 80%.

Electrical Design

As mentioned, the design of the magnetic amplifier revolved around the resolution of the rectifier inverse voltage rating, the required maximum d-c output voltage, and the total residual phase inductance of the system. The limitations upon the transformer secondary voltage are obvious. If 33-volt inverse selenium cells are chosen, the maximum allowable line-to-neutral secondary voltage will be $33/1.73 = 19$ volts, with sufficient load to cause the interphase to insure double half-wave action. With perfect rectifiers and reactors the minimum line-to-neutral voltage for a 14-volt d-c output must be $14 \times 0.855 = 12$ volts.

Design Procedure

The usual design procedure is to start with the minimum required a-c secondary voltage for the maximum desired d-c output (maximum voltage and current) and add the proper allowances to compensate for selenium cell drop, system *IR* voltage drop, and an assumed phase reactance potential loss. For the transformer voltage determined in the foregoing manner, the reactor size necessary to absorb sufficient voltage to allow minimum d-c output can be computed. With the reactor dimensions determined, its voltage drop at maximum load can be computed and checked against the original allowance used to determine the transformer secondary voltage. With this procedure a secondary transformer line-to-neutral voltage of 17.1 volts was established. The check of this value is as follows: An a-c forward voltage drop of 1.5 volts was assumed for the selenium cells at 40,000 amp per unit. The useful alternating voltage after rectifier drop becomes

$$17.1 - 1.5 = 15.6 \text{ volts rms} \qquad (1)$$

This voltage can now be converted to its equivalent d-c output value through division by the 3-phase, half-wave conversion factor

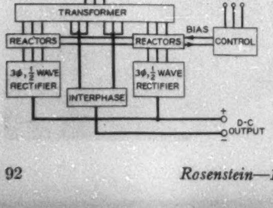

Fig. 3 (left). Elementary block diagram for one unit

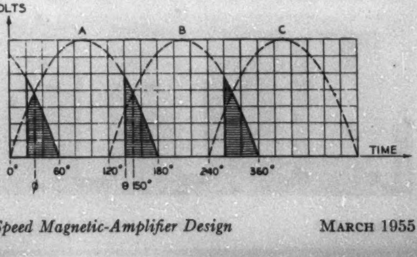
Fig. 4 (right). Theoretical minimum output voltage wave shapes



Vol. 7
Pt. 1
1955

$$E_{do}=\frac{E_{ac}}{0.855}=\frac{15.6}{0.855}=18.2 \text{ volts} \qquad (2)$$

The total d-c IR drop of the unit including the equivalent transformer resistance was computed at 0.5 volt. Subtracting the IR drop and the desired maximum d-c output voltage from E_{do} will give ΔE_{do}, the total allowable commutating phase reactance voltage drop

$$\Delta E_{do}=18.2-0.5-14=3.7 \text{ volts} \qquad (3)$$

The general expression for ΔE_{do} is given by equation 4, where L includes all inductance per phase of each 3-phase, half-wave section, including the equivalent transformer leakage inductance, the reactor residual (i.e., saturated) inductance, and the total lead inductance per phase

$$\Delta E_{do}=\frac{p\omega LI_0}{2}=3fLI_0 \qquad (4)$$

where

f = supply frequency
L = total inductance
I_0 = average current (20,000 amp maximum per section)

Computing L for maximum load

$$L=\frac{\Delta E_{do}}{3fI_0}=\frac{3.7}{3\times 60\times 20{,}000}=1.03\times 10^{-6} \text{ henry} \qquad (5)$$

The magnitude of 1-microhenry inductance can be better appreciated by computing the inductance of a single-turn inductance with a radius of 1 meter and a conductor cross section of nominal area

$$L\cong\frac{\mu N^2\pi r}{2} \text{ for a simple circular coil}$$

$$L=\frac{12.56\times 10^{-7}\times 1^2\times \pi\times 1}{2}=2\times 10^{-6} \text{ henry} \qquad (6)$$

where

$\mu = 12.56\times 10^{-7}$ for free air
r = radius, meters

PHASE INDUCTANCE

Therefore, the total allowable phase inductance must be less than the inductance of a simple single-turn coil with a 1-meter radius. The components of the phase inductance were determined as follows: By careful design the equivalent reactance of the transformer was held to less than 1.0% or 0.05 microhenry. The lead inductance was estimated at 0.3 microhenry, although the complicated geometry made an exact determination difficult. The saturated reactor inductance was computed with approximately 400 ampere turns (a-t) of positive bias where the core curves of magnetic induction versus magnetic intensity (B-H) indicate that an additional 20,000 a-t will cause a core flux density change of 35,000 lines per square inch. The reactors were designed with one turn and a core area of 36 square inches. The reactor saturated inductance then became

$$L=\frac{N\Delta\phi}{I}=\frac{1\times 36\times 35{,}000\times 10^{-8}}{20{,}000}=0.63 \text{ microhenry} \qquad (7)$$

The total phase inductance = 0.05 + 0.3 + 0.63 = 0.98 microhenry or just within the allowable 1.03 microhenry. The steps taken to reduce the mechanical loop circumscribed by each phase and consequently the phase lead inductance to a minimum will be described in the section "Mechanical Design."

REACTOR DESIGN

The final electrical characteristics of the reactors were partially dictated by the combination of the low value of saturated reactor inductance required and the saturated characteristics of the reactor core material chosen. For a given kva, the saturated reactor inductance varies almost directly with the reactor turns. This means that a 2-turn reactor has one half the core area of the single-turn reactor, but possesses close to twice the saturated inductance, or in this case approximately 1.2 microhenrys. The final reactor dimensions can now be determined from consideration of the reactor requirements for minimum output voltage and current.

Minimum load conditions were 2 volts at 10,000 amp per unit. Final reactor design procedure calls for a check of the a-c reactor voltage that must be absorbed to achieve the desired minimum output against the maximum alternating voltage that can be absorbed by the chosen design. Since other voltage drops, including that of the selenium cell, still exist, the reactors do not have to absorb all the 17.1 volts available. The total alternating voltage that must be absorbed by all elements can be determined from a consideration of Fig. 4, which shows the output wave form of a perfect 3-phase, half-wave magnetic amplifier for 1 complete cycle. Since the average areas under the heavy wave give the d-c output, the firing angle of phase A can readily by computed for a 2-volt d-c output

$$\frac{3\times E_{max}}{2\pi}\int_{\theta}^{2\pi}\sin \times dx=E_{dc}$$

$$\int_{\theta}^{2\pi}\sin \times dx=\frac{2\times 2\pi}{3\times 1.414\times 17.1} \qquad (8)$$

$$-(\cos\theta-1)=17.3$$

$$\theta=180°-34.3°=145.7°$$

The volt radians absorbed by the reactor and associated elements of phase A must equal the area under voltage curve A less the shaded area when phase C or A have fired. For this particular machine, the IR and reactive drops will require phase C to fire well before time ϕ so the following figure for the volt radians that must be absorbed will be slightly conservative

$$\text{Area under wave } A=E_{max}\int_{\theta}^{2\pi}\sin \times dx=2\times 1.414\times 17.1=48.3 \text{ volt radians} \qquad (9)$$

$$\text{Area not absorbed}=2xE_{max}\int_{\theta}^{2\pi}\sin \times dx=2\times 1.414\times 17.1(1-34.30 \text{ degrees})=8.38 \text{ volt radians} \qquad (10)$$

$$\text{Area absorbed}=48.3-8.38=39.9 \text{ volt radians}$$

The equivalent rms voltage that must be absorbed is, of course, directly related to the volt radians.

$$\text{Rms voltage to be absorbed}=17.1\times\frac{39.9}{48.3}=14.1 \text{ volts} \qquad (11)$$

This voltage must be absorbed by the reactors, the inductive drop, the IR drop and selenium cell voltage loss.

With grain-oriented cores, the reactors are capable of sustaining a maximum flux density of 125,000 lines per square inch. With one turn and 36 square inches of core cross section, the reactors could each absorb

$$E=4.44Nf\phi\times 10^{-8}=4.44\times 1\times 60\times 36\times 128{,}000\times 10^{-8}=12 \text{ volts rms} \qquad (12)$$

At 5,000 amp per section, the lead and transformer induction drop becomes equivalent to 0.38 volt rms. The total selenium cell and IR voltage drop was estimated to be 1.3 volts. The total maximum voltage that can be absorbed adds up to 13.68 volt rms. It is to be noted that the maximum voltage of 13.68 volts which can be absorbed is slightly less than the 14.1 volts which must be absorbed to reduce the output to 2 volts direct current. Rather than increase the reactor size through the use of nonstandard cores, it was possible to use the two plus $2^1/_2$% transformer primary taps to reduce the secondary voltage to 16.3 volts rms. With the reduced secondary voltage it becomes necessary to absorb only 13.4 volts, leaving a small operating margin.

CONTROL DESIGN

The design of the reactor control windings requires correlation of the core material magnetization characteristics, core dimensions, control power source characteristics, desired power gain, desired response speed, and insulation requirements for the maximum inducted control-winding voltage. The reactor cores were composed of standard Hypersil *C* loops with an effective magnetic path of 33 inches. From the core magnetization curves, it was observed that 400 a-t corresponded to a point well beyond the knee of the saturation curve, while 100 a-t came well into the knee of the curve. The electronic control tubes available could conveniently supply 500 ma. A control winding of 800 turns with 500 ma would supply the desired maximum output, while 200 turns at 500 ma could supply the rated overload current at output voltages up to 11 or 12 volts. The minimum output could likewise be reached with 400 a-t of negative bias. To meet readily the full range of required operating conditions, the reactors were built with four 200-turn control windings with individual termination for series or parallel connection.

Since response was guaranteed to be within $1^1/_2$ to 3 cycles, the control system and control windings were carefully designed for maximum speed of response. Using the expression $L=N\Delta\phi/\Delta I$, the average inductance of the control when connected for 200 turns was computed to be 64 henrys. This figure dictated a 1,000-volt control power supply. The series resistance at 500 ma is 2,000 ohms and the control time constant becomes $64/2{,}000=0.032$ second or 1.92 cycles. Further to insure a maximum speed of response, the control current was regulated by series pentodes with a large amount of negative feedback. The pentodes act as constant current generators up to the point where rate of current increase approaches E_s/L. It should be noted that for operation at maximum output with 800 turns, the inductive control will not increase with the square of turns because of the nonlinearity of the magnetic core and the fact that at high outputs, one-third of the reactors are always conducting.

A quick check upon relative response for the conventional self-saturating magnetic amplifier can always be obtained from the over-all power gain of the amplifier. In this case an input change of 500 ma at 1,000 volts, 0.5 kw, was estimated to give the double power cycle with an 890 kw change in output power. A 1,980/1 power gain with less than 2-cycle response can be expected from a 3-phase self-saturating magnetic amplifier.[1]

In any large-power, fast-responding magnetic amplifiers, adequate instant high-voltage insulation must always be provided for the control windings. In this case, the maximum possible instantaneous voltage which could be coupled from the power winding to the control would be $2\times17.1\times200\times4=27{,}400$ volts per winding. Although 10,000-volt insulation was provided between control windings and to ground, the maximum possible coupled voltage was further reduced in several ways. First, each reactor was constructed of six Hypersil loops. The control winding encircled only two loops at a time so that each reactor had three sets of d-c coils of four 200-turn windings. For each 200-turn winding, the maximum coupled voltage becomes $2\times17.1/3\times200=2{,}280$ volts. Since the coupled control voltage of the reactors add phasorily when the winding of the various phases are connected in series, the net coupled voltage of all of the first 200 turns of the first section of all reactors would theoretically be zero. Since each reactor has three sets of windings, each 200 turns of control consists of $6\times3=18$ windings in series. To prevent an excessive inducted control winding potential from a rapidly reduced control current, Thyrite resistors were connected across the control input to each of the 30,000-amp sections.

To realize safely the full intermittent magnetic amplifier rating of 160,000 amp, it was necessary to balance carefully the magnetic characteristic of each reactor against the other reactors in its section. The magnetic characteristics of all sections were to be reasonably uniform so that less than 5% load unbalance between sections could be conveniently achieved. Each Hypersil loop was individually graded before and after installation. Characteristics were compared, and matched sets of six were selected. The final over-all reactor core characteristics were held to within $\pm2^1/_2\%$.

TRANSFORMER DESIGN

The low reactance and unusual mechanical requirements governed the transformer design. With a 12,800-volt input and 17.1-volt, high-current output, a thoroughly interleaved pancake construction was necessary. Because of the heavy currents, a single-turn secondary was used.

The necessity for relatively close coil spacing coupled with the coiling requirements of the rectifiers and further specification of a self-contained outdoor construction, made oil cooling and insulation attractive. With a closed cooling system, the possibility of high-voltage failures from the dirt and moisture that air cooling would accumulate on the transformer windings was eliminated. The transformer primary was tapped for $\pm2^1/_2$ and $\pm5\%$. The positive taps insured light-load 2-volt operation, while the negative taps were available for maximum output in case of rectifier aging.

RECTIFIER DESIGN

The rectifying elements of the magnetic amplifier were half-wave selenium stacks. Each 3-phase, half-wave section consisted of 6 half-wave stacks giving 2 stacks per phase and 12 stacks per unit. A total of 7,776 plates of 45 square inches (each $6^1/_4$ by $7^1/_4$ inches) were used to give an average oil-cooled current density of 0.344 amp per square inch.

Although 33-volt inverse cells were used, there was considerable speculation about the possibility of cell failure due to a high inverse voltage. It was believed that the cell manufacturer's inverse rating was conservative but required the failure of only 1 out of the 7,776 parallel plates to render the equipment inoperative. Further, if the equipment were energized with zero load, the inverse voltage would become twice the line-to-neutral voltage, or 34.2 volts instead of 1.73 times the secondary potential.

Four possible modes of cell failure, current overload, chemical, inverse voltage overheating, and inverse voltage barrier breakdown, presented themselves. Under continuous overload, the cell would overheat, the backing metal of the cell would melt, and the cell would be damaged or destroyed. However, with forced oil cooling, the possibility of individual cell overheating becomes negligible without materially increasing the oil temperature. Thermal overtemperature contacts were installed in the oil to turn the magnetic amplifier off well before a critical temperature could be reached.

Chemical elements in the oil could attach the selenium cells. A particularly pure neutral oil (without neutralizing chemicals) was specified and a regular check schedule established to insure that the neutralization number never exceeded 0.01 milligram of KOH. Above 0.01, the oil was to be discarded. Overheating caused by the high inverse currents of excessive inverse voltages would be prevented by the oil cooling.

Cell breakdown due to high inverse voltage failure of the barrier layer represented the only unknown factor in the cell reliability problem. To obtain some idea of the dependability of selenium cells under excessive inverse voltage, a random selection of twelve 33-volt cells was immersed in oil and subjected to slowly increasing inverse voltages. than a marked increase in inverse leakage current, there were no visible detrimental effects up to 42 volts. At 43 volts plate 9 sputtered once and cleared itself. No further effects were observed until the inverse voltage reached 51 volts where plate 2 sputtered. Plate 2 was observed to be extremely hot and was removed from the circuit. The remaining plates were subjected to 51 volts inverse for 20 minutes with only one sputter, which cleared itself. The inverse current at 51 volts was approximately 2.1 amp per plate, causing a loss of 107 watts per plate. These tests indicate that the oil-immersed selenium cell can be subjected to extreme overvoltage without destruction. In an attempt to destroy the cells, inverse voltages up to 84 volts rms were applied. Above 64 volts, the sputtering increased rapidly, but none of the cells were completely destroyed. Examination of the plates during and after the test indicates that very high increase voltages will cause random point failures in the cell barrier. When the barrier fails at a point, a very high current will immediately flow through the break, causing extreme local temperatures which vaporize the selenium at the point and cause it to blow itself clear. The average failure will blow out an area approximately 1/4 inch in diameter. The rest of the plate will be unaffected by this localized failure. Plates subjected to 84 volts inverse lost up to 50% of their active rectifying area.

Interphase Reactor

The electrical design of the interphase reactor was straightforward. For part standardization, the core of the interphase was constructed from three of the saturable reactor Hypersil loops. The mechanics of this problem forced the use of a 2-turn center-tapped construction. With the extreme phase shift introduced by the magnetic amplifier reactors, the maximum 180-cycle voltage across the reactor will be considerably greater than the theoretical voltage of the simple rectifier circuit. With the higher frequency, the interphase was designed for a lower maximum flux density.

The size of the output bussing of the magnetic amplifier is perhaps of some interest. For the high-current connection, the current was fed through parallel 1/2 by 6-inch water-cooled bus to the center of the array where the total current was supplied to the load through 12 copper bus bars each 1/2 by 12 inches.

All controls for the equipment were assembled in a single floor-standing cabinet. In the schematic diagram, Fig. 5, for the magnetic amplifier, none of the protective equipment is indicated. The control windings (sometimes called bias windings) were supplied from self-biased series vacuum tubes. Separate negative and positive bias tubes were provided. Current flow through the tubes was adjusted by varying the self-biasing cathode resistors. A motor-driven variable eccentric cam was provided to switch automatically the double or triple power cycle by biasing the positive bias tubes in and out of conduction.

The need for remote indication and the inconvenience of conventional shunts suggested the use of current transductors for d-c measurement. The current transductors were permanently installed within the tank of each section. The transductors enclosed the output bus of the section so that the average alternating current in the transductor was in direct proportion to the d-c output current. To use a linear scale, the a-c transductor current was rectified and applied to 5-amp d-c instruments. Thyrite disks were connected across the transductor windings to limit any inducted voltage surges.

MECHANICAL DESIGN

The mechanical design of the magnetic amplifier was largely predicated upon the needs for minimum-size and minimum-phase inductance. The equipment was transported from Los Angeles to the Midwest on special low-bed trucks. Even at that, road clearances along the way were such that the high-voltage bushings had to be removed. To keep the tank size and lead inductance to a minimum, the transformer, reactors, interphase, and stacks were made as an integral assembly that bolted into the tank as one piece. Figs. 6(A) and (B) illustrate the basic mechanical construction without detailing all of the bracing. Fig. 1 shows a section of the magnetic amplifier being lifted by a crane for entanking.

TRANSFORMER

The transformer, being the heaviest component, was used as the foundation for the magnetic amplifier assembly. The transformer was further laid on its side with the high-voltage leads and primary tap switch on the bottom. The low-voltage secondary leads were extended from the other side or what was now the top of the transformer. To maintain the desired low transformer reactance, the primary and secondary pancake windings were thoroughly interleaved. Each leg of the transformer contained a primary phase winding and two secondary sets of coils to supply the double-wye magnetic amplifier. The pancakes of one secondary set were collected on one half of the transformer leg, while the other secondary set occupied the other half. The separation was maintained up through the magnetic amplifier structure and the two sections were paralleled at the positive output bus and at the interphase.

REACTORS

The reactors were mounted directly upon the transformer and supported by a noninductive structure. The selenium rectifiers were assembled in a metal housing and in turn mounted directly on top of the reactors. The two neutral busses were mounted one on each side of the reactor assembly and fed into the interphase assembly which was supported on the low-voltage end of the transformer. After each assembly was bolted into its tank, it was only necessary, after putting the oil baffles in place, to install and connect the d-c terminals and high-voltage a-c bushings.

The limitations of minimum head room and the need for heavy-current connections between transformer, reactors, and selenium rectifiers presented a serious mechanical problem. On each phase the outputs of a group of pancake windings had to be collected and paralleled. The transformer secondary copper per phase collected into a bundle 3/4 inch thick by 9 inches wide. Rather than attempt to terminate the transformer secondaries and then connect to a heavy reactor bus, the transformer secondary windings were left approximately 40 inches long on each end. These ends were collected into 9- by 3/4-inch bundles to form vertical copper risers. The six Hypersil loops that formed each reactor had a window of $2^1/_8$ by 11 inches and were of the cut-core type. These loops were separated and assembled with their d-c control coils in pairs around six of the twelve risers. The ends of the reactor risers were then formed over, collected into smaller bundles, and lugged for bolting to the input bus of their respective rectifier stacks. The transformer secondary leads thus became the 1-turn power winding of the reactors. The remaining six vertical risers formed the neutral leads of the 3-phase, half-wave connection. To keep the secondary inductance to a minimum, the neutral leads were brought up as close to their corresponding reactor lead as possible and then formed over to the neutral bus.

RECTIFIERS

Each assembly contained 12 selenium stacks, or two stacks per phase. Each stack contained 162 plates each $6^1/_4$ by $7^1/_4$ inches connected in parallel. These stacks were reported to be the largest of their type manufactured to date. The 12 stacks per unit were assembled into a common housing with six stacks (two per phase) on each side. Further to reduce the secondary inductance, the phase connections to six stacks were thoroughly transposed.

INTERPHASE

Electrically, the interphase reactor consisted of two turns, center-tapped. Mechanically, the interphase was used to provide the connection from the two neutral busses to the negative output terminal. Since each conductor of the reactor had to carry an average of 15,500 amp, it was necessary to utilize all of the $2^1/_8$- by 11-inch window of the reactor cores. The connection between the neutral bus and output terminal (which also became the windings of the interphase reactor) consisted of a pair of high-purity copper castings. These castings were provided with leaves on either end which simultaneously interleaved with the terminals of the neutral bus and the negative output terminal.

Because of the cost and bulk of the oil-to-air heat exchangers, the efficiency of the magnetic amplifier was of prime im-

Table II. Results of 1951 Magnetic-Amplifier Acceptance Tests

Type of Test	D-C Output	A-C Supply	Control	Response*	Efficiency

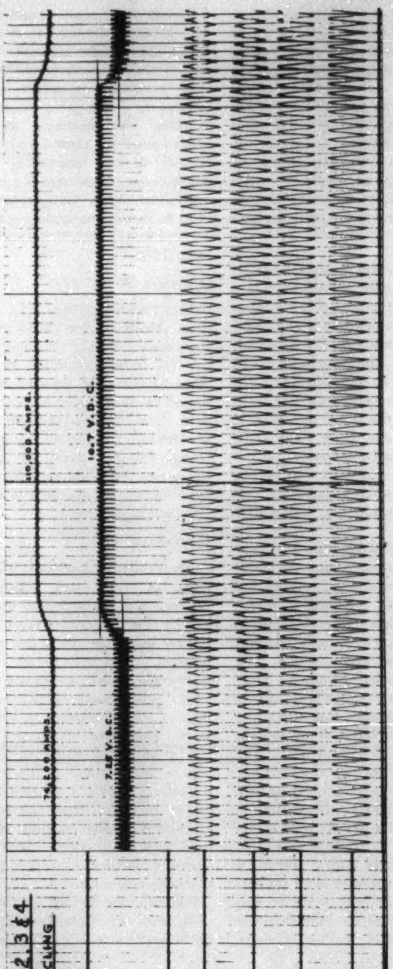

Fig. 7. Oscillographs of double power cycle

portance. Exclusive of auxiliary losses, the main losses in the amplifier consisted of selenium rectifier loss, transformer losses, and circuit *IR* losses. The stack drop was assumed to be the equivalent of 1.5 volts of applied alternating voltage. The total transformer losses (four units) at rated load and 14 volts direct current were computed to be 80 kw. The equivalent circuit d-c *IR* drop was computed at 0.2 volt.

$$\text{Computed magnetic amplifier efficiency} = \text{stack efficiency} \times \text{transformer efficiency} \times \text{d-c efficiency} = \frac{14.2\times0.855}{14.2\times0.855+1.5}\times\frac{1{,}950}{1{,}950+80}\times\frac{14}{14+0.2}=84.3\% \quad (13)$$

Test Data

Table II summarizes the pertinent results of the magnetic amplifier acceptance tests which were conducted late in 1951. The minimum load and rated load tests meet all specifications and, as was expected, the transformer primary taps were of assistance in meeting the extremes. The nominal range test was listed to show the output range readily available with 200 turns of bias winding and a single fixed transformer tap setting. In this case a change in control current from 348 ma minus to 300 ma positive swung the output voltage from 3.7 to 11.5 volts. For the double-power response test, the automatic cycling control switched the output voltage from 7.25 to 10.7 volts and the output kw from 538 to 1,176. The voltage and current oscillographs of the response test are shown in Fig. 7 where each vertical spacing represents 1 cycle. When the output voltage is switched from 7.25 toward 10.7 volts, the graph shows that the output voltage covers approximately 63% of the change in about 1.5 cycles. In switching from 10.7 to 7.25 volts, this is seen to be even less than 1.5 cycles. Although the oscillographs were taken for only three units, operation of the full magnetic amplifier would still give a response time of 2 cycles or less. Parallel operation of the units proved to be particularly successful. With loads of 120,000 amp, load division between units of ±1% was achieved in operation.

Although power gain was sacrificed for response in the double power test {the control supply voltage was 1,100 volts and the power gain $=[(1{,}176-538)1{,}000]/(1{,}100\times683)=1{,}023/1$}, the maximum possible power gain from the magnetic amplifier was substantial. For example, if the four 200-turn windings were connected

Vol. 7
Pt. 1
1955

in parallel, the total resistance would have been 15 ohms for three units. For the double-power test, the control power change would have been $0.685\times 15=7.03$ watts and the power gain would equal $638{,}000/7.03=90{,}500/1$.

Conclusion

The static magnetic amplifier described is, we believe, the largest of its type built to date. In this case, an application requiring the control of reasonably large blocks of power, which did not seem to lend itself to rotating magnetic amplifiers or other forms of power control, was satisfied with a static magnetic amplifier. The static magnetic amplifier met or exceeded all specifications. The speed of response of $1^{1}/_{2}$ to 2 cycles was well below that of comparable rotating amplifiers. The efficiency was high and the space requirements, in regard to the outdoor construction, were quite nominal. Maintenance and service have proved negligible.

The power application future of the static magnetic amplifier should be bright. Where dependability is at a premium, such as, e.g., in central generating stations, the static amplifier with its absence of moving and wearing parts should often replace the rotating amplifier. It is expected that with the demonstration that there are few size limitations upon static amplifiers, designers will find, that completely static excitation systems will further improve large alternator dependability.

The over 82% efficiency of the machine described is higher than can be achieved by other types of equipment at these low voltages. With selenium cells, static amplifier efficiencies of 80 to 85% can be expected with careful design at output potentials from 14 volts up to practically any desired voltage. At over 100 volts, the efficiency of the d-c static amplifier with selenium cells begins to be exceeded by other forms of equipment. However, this disadvantage of the static machine is only temporary. Silicon and germanium power rectifiers have now been developed to the point where engineers are designing large static magnetic amplifiers with efficiencies approaching 95%.

The advent of low-cost silicon and germanium power rectifier cells assures the extensive application of both d-c and a-c static magnetic power amplifiers. With the high gain of the self-saturating circuit, the amplifier reactor size becomes less than that of an autotransformer controlling comparable power. The new silicon or germanium power cells are considerably smaller than their controlling reactors. The static magnetic amplifier can therefore be manufactured with a smaller bulk and a cost that approaches that of a 2-winding transformer of the same rating. With high efficiency, extreme dependability, low weight, minimum bulk, and reasonable cost, the static magnetic amplifier will pre-empt much of the electrical field which are now served by other machines.

STUDENT MEMBER AIEE

Synopsis: A magnetic frequency multiplier circuit operating from a 60-cycle-per-second (cps) 3-phase supply and delivering an approximately sinusoidal output at a frequency of 180 cps consisting of three identical nonlinear reactors of Deltamax cores inductively loaded is analyzed and a simple design procedure is outlined. The particular case of triple multiplication is chosen for convenience. The method of analysis may be extended to higher frequencies, either by using higher supply frequency or by using more phases. The power capability of the system depends upon the size of the cores, thus efficient multipliers for any desired power output may be designed.

IN EARLY days the need for higher frequencies for radio transmission aroused a considerable interest in frequency multiplication. The methods used were numerous. Broadly speaking, these may be divided into three classes, namely, machine, induction, and electronic apparatus. The machine type employ rotating parts while the induction type have the important advantage of being static where iron cores are electromagnetically excited in such a manner as to be periodically saturated, producing harmonics which are delivered to tuned loads. They are superior to electronic multipliers in that they use no tubes or rectifiers. Consequently, they are rugged, efficient, and can deliver large quantities of power.

During World War II, magnetic amplifiers became popular and extensive research on magnetic core materials was performed, yielding very high quality cores with almost rectangular hysteresis loop. The use of such cores as components for magnetic devices improves the performance and simplifies analysis and design. Thus using such cores, it is possible to build very efficient frequency multipliers having reliability and long life.

The circuit analyzed is similar to that of reference 1 where multipliers with tuned loads of power ratings ranging from 1 to 300 watts and with multiplication values ranging from 3 to 10 were mentioned. The analysis given in this reference went as far as deducing a relationship between applied voltage and firing angle. However the important fact that the relationship derived was based on the assumption of resistive loading was not pointed out. This relationship is gov-

erned by the type of the load which must be specified as the first step towards analysis. In this paper the performance of a small unit for the cases of resistive and inductive loading is predicted mathematically and confirmed with measured results. The equations deduced are general and may be applied to multipliers of any size.

Equation 1 relates the conduction angle and applied voltage for the case of resistive loading and shows good correlation with practical measurement as seen in Fig. 8. However when this equation is converted to the appropriate form to be compared with the equation of reference 1 relating the firing angle and applied voltage the values do not check with the latter. The reason for this discrepancy is that the constant of integration corresponding to K_1, which represents the initial flux density at the instant of the start of the positive half-cycle of the supply voltage was taken to be zero; see Appendix I. This is not true since the reactor at this instant is still saturated in the negative direction caused by the preceding negative half-cycle of the supply voltage.

Circuit and Assumptions

The experimental circuit of Fig. 1 consists of three identical nonlinear reactors *C* with Deltamax cores of magnetization characteristics as shown in Fig. 2. Each reactor is fed in series with a common load consisting of the load resistance R_L and a smoothing linear reactor L_e from one of the phases of the 3-phase power supply through an isolation transformer *T* and a variac *V* providing the facility of changing the applied voltage. The equivalent circuit is shown in Fig. 3.

For the purpose of analysis the multiplier circuit is treated as three independent basic circuits, Fig. 4, each connected to the load separately and representing a branch of the multiplier circuit. The validity of this assumption follows from the fact that the nonlinear reactor of each basic circuit behaves in a manner similar in some respects to a gas tube. Thus, the current flows only for a portion of the cycle, the conduction angle depending upon the magnitude of the applied voltage. This assumption is not exactly true, however, for the experimental reactor of Fig. 5; the magnitude of the current which would flow outside the range of conduction is almost negligible, i.e., the impedance of the circuit to the flow of current is high compared with the conduction impedance. Consequently, since the applied voltages are displaced by 120 degrees, during the interval in which one of the basic circuits is conducting the remaining two are not, offering a very high impedance to the flow of current so that, when three of such circuits are connected to form a multiplier, the interaction between the branches is almost negligible and the multiplier output is simply equal to the sum of the outputs of the three circuits when each is connected to the load separately. This is true provided that the conduction angles for the basic circuits are equal to or less than 60 degrees of the supply voltage. The validity of this assumption may be seen from Fig. 6.

The assumptions made in analyzing the basic circuit of Fig. 4 are:

1. The winding resistance of the nonlinear reactor and the external linear reactor may be lumped with the load resistance.
2. The distributed and the winding capacitances of the reactors are negligible.
3. For high values of saturation current which apply to this case, the magnetization current, the eddy current, and the hysteresis losses are negligible and the magnetization characteristic may be represented, as shown in Fig. 7.

Current Wave Shape for the Case of Resistive Loading

The current flowing in the basic circuit of Fig. 4 for the case of resistive loading is a portion of a sinusoidal current which would flow when the saturable reactor is substituted by a resistance equal to its winding resistance. The current wave is shown in Fig. 8 and, to define it completely, the relationship between applied voltage and conduction angle must be known. This is derived in Appendix I and is

$$E = \frac{\sqrt{2} A B_c N \omega}{10^8} \left(\frac{1}{1 + \cos \alpha_c} \right) \tag{1}$$

To check the validity of this relationship, calculated values of E corresponding to different values of conduction angle are plotted in Fig. 9 together with measured results obtained from oscillograms of Fig. 10 which show good agreement.

The output of the tripler for the case of resistive loading contains only odd harmonics of three times the supply frequency. A Fourier analysis of the output is given in reference 2 where a general equation is derived by which the phase and amplitude of the harmonics corresponding to any value of conduction angle may be calculated.

Current Wave Shape for the Case of Inductive Loading

The output of the multiplier for the case of resistive loading is not sinusoidal and, as this requirement is essential for the output, several attempts have been made to attain sinusoidal approximation. Using a tuned output, the desired harmonic may be filtered; however, the addition of a smoothing inductance in series with the load is the simplest method to achieve this approximation. To estimate the value of the inductance necessary for an acceptable output wave shape,

Fig. 13 (right). General graphical solution for current for the case of inductive loading

several oscillograms for the output current of the basic circuit were observed corresponding to different values of Q, while the conduction angle was fixed at 60 degrees by adjusting the applied voltage. These oscillograms are shown in Fig. 11, indicating that the output will approximate a sinusoid closely when Q is increased sufficiently. However, the addition of inductance will decrease the amplitude of the output. Thus, in choosing a suitable value for Q, a compromise should be made. In the authors' opinion, a convenient value to be chosen for Q is 0.5 which will be taken as the basis for the subsequent analysis.

The wave shape of the current corresponding to a given conduction angle is to be determined. This may be done in two steps: first, by deducing the relationship between applied voltage and conduction angle; and secondly, by deducing the relationship between this angle and the current.

RELATIONSHIP BETWEEN APPLIED VOLTAGE AND CONDUCTION ANGLE

This relationship is derived in Appendix I and is

$$E=\frac{\sqrt{2}AB_cN\omega}{10^8}\times$$

$$\left[-\frac{1}{\cos\left[\phi+\tan^{-1}\left(\dfrac{\sin\alpha_c}{e^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)+\alpha_c\right]+\cos\left[\phi+\tan^{-1}\left(\dfrac{\sin\alpha_c}{e^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)\right]}\right] \quad (2)$$

An examination of the relationship derived shows that for a fixed Q, changes in R and the corresponding changes in L do not affect the conduction angle.

To check the validity of equation 2, calculated values of E corresponding to different values of conduction angle are plotted in Fig. 9 together with measured results obtained from oscillograms of Fig. 12 which show good agreement. From the graphical relation of Fig. 9, the following conclusions may be made:

1. The critical voltage at which firing takes place is a characteristic of the reactor and is independent of load condition.
2. For a given applied voltage higher than the critical value, the presence of inductance in the load increases the conduction angle, thus making the reactor more sensitive to voltage changes.

RELATIONSHIP BETWEEN CONDUCTION ANGLE AND CURRENT WAVE SHAPE

The differential equation describing the operation of the basic circuit in the saturation region is of the form

$$L\frac{di}{dt}+R_i=\sqrt{2}E\sin\omega t$$

The solution of this differential equation is carried out in Appendix II. The expression derived for the current is

$$i=\frac{\sqrt{2}E}{(R^2+\omega^2L^2)^{1/2}}\times$$

$$\left[\sin(\omega t-\phi)-\sin\tan^{-1}\left(\frac{\sin\alpha_c}{e^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)e^{-\frac{R}{\omega L}\left[\omega t-\phi-\tan^{-1}\left(\frac{\sin\alpha_c}{e^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)\right]}\right] \quad (3)$$

Substituting for the value of E given by equation 2, a general expression for the current is

$$i=\frac{2AB_cN\omega}{10^8(R^2+\omega^2L^2)^{1/2}}\times$$

$$\left[-\frac{1}{\cos\left[\phi+\tan^{-1}\left(\dfrac{\sin\alpha_c}{e^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)+\alpha_c\right]+\cos\left[\phi+\tan^{-1}\left(\dfrac{\sin\alpha_c}{e^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)\right]}\right]\times$$

$$\left[\sin(\omega t-\phi)-\sin\tan^{-1}\left(\frac{\sin\alpha_c}{e^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)e^{-\frac{R}{\omega L}\left[\omega t-\phi-\tan^{-1}\left(\frac{\sin\alpha_c}{e^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)\right]}\right] \quad (4)$$

From this expression the wave shape of the current corresponding to any value of conduction angle may be determined showing that, for a fixed conduction angle corresponding to a fixed applied voltage, provided $Q=\omega L/R$ remains constant, the changes in L and the corresponding changes in R only affect the amplitude of the current but do not change the wave shape.

An analytical solution for the current involves tedious calculations. Using graphical methods and introducing some approximations, an expression for the current may be deduced readily. Equation 3 is represented graphically in Fig. 13 for the general case and in Fig. 14 for the particular case of interest where $Q=0.5$ and $\alpha_c=60$ degrees, indicating that the current wave shape for this case may be approximated fairly closely to a sinusoidal current having a maximum value of $I_{0\text{ max}}$ where

$$I_{0\text{ max}}=0.260\,I_{\text{max}},\ \text{and}\ I_{\text{max}}=\frac{\sqrt{2}E}{(R^2+\omega^2L^2)^{1/2}}$$

The value of the applied voltage E depends upon the conduction angle and is given by equation 2, which is represented graphically in Fig. 15, using $E/AN\omega$ as the ordinate. This graphical relationship is general and may be applied to any size of reactor with Deltamax cores, and the value of E corresponding to a conduction angle of 60 degrees may be found. Demoting this voltage by E_{60} and letting $\omega L=R/2$, the expression for the maximum value of the approximate sinusoidal current for any reactor reduces to

$$I_{0\text{ max}}=0.328E_{60}/R$$

and the rms value

$$I_0=0.232\,E_{60}/R \quad (5)$$

To study the effect of connecting three of the basic circuits to form a multiplier, oscillograms of the output wave shape for each circuit connected to the load separately were taken; in each case the conduction angle was adjusted to 60 degrees. Finally, the multiplier circuit was connected and a fourth oscillogram was taken. These oscillograms are shown in Fig. 6 which clearly indicates that the interaction between the branches is negligible; thus, the output of the multiplier is practically the sum of the outputs of the three circuits and is approximately sinusoidal.

Power and Efficiency

To fulfill an approximately sinusoidal output requirement the Q for each of the basic circuits and the conduction angle are fixed at 0.5 and 60 degrees respectively throughout; thus, the applied voltage is constant at E_{60}. For any changes in R, a corresponding change in the value of L is assumed to be made such that Q remains constant. Such changes will affect neither the firing angle nor the general wave shape of the output current; they merely alter the amplitude of the latter. Thus, the output current may be assumed approximately sinusoidal throughout these changes, the rms value of which is given by equation 5.

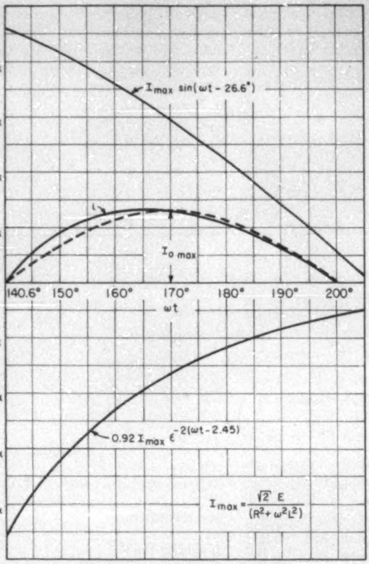

Fig. 14. Graphical determination of current i for the case of inductive loading, $Q=0.5, \alpha_0=60$ degrees

Assuming the resistance of the smoothing reactor to be a part of the load, the power output of the multiplier is

$$P=I_0^2R_L=0.0538\,\frac{E_{60}^2R_L}{(R_\omega+R_L)^2} \qquad (6)$$

From this equation it may be concluded that the maximum power $P_{\max}$ is delivered to a load having a resistance equal to the winding resistance of the reactor where

$$P_{\max}=0.0134\,\frac{E_{60}^2}{R_\omega} \qquad (7)$$

From equations 6 and 7

$$\frac{P}{P_{\max}}=\frac{4R_\omega R_L}{(R_\omega+R_L)^2}$$

For high values of load current the presaturation current is negligible and the expression for efficiency may be written as

$$\eta=\frac{R_L}{R_\omega+R_L}\times 100 \text{ per cent}$$

Values of $P/P_{\max}$ and η corresponding to different values of R_L are plotted in Fig. 16. It must be pointed out that these relations are only true for the limited range of operation where the presaturation current is negligible compared with the saturation current.

Design and Calculations

Given three identical Deltamax cores, the windings may be designed as follows:

1. From Fig. 15, the value of $E/AN\omega$ corresponding to 60 degrees may be found.
2. Deciding on a suitable value for E_{60} and knowing ω and A, the number of turns N may be calculated.
3. From tables a suitable wire size may be chosen to fill the available window area, and the resistance of the windings may be found.
4. From efficiency and power curves of Fig. 16, a suitable operating point may be chosen so that the value of the load resistance may be calculated.
5. The inductance of the winding at saturation is usually less than the value required for a $Q=0.5$, thus sufficient external inductance may be added to fulfill this requirement.
6. Making use of equation 7 and Figs. 15 and 16, the output power of the multiplier may be calculated.

The process of design may be reversed

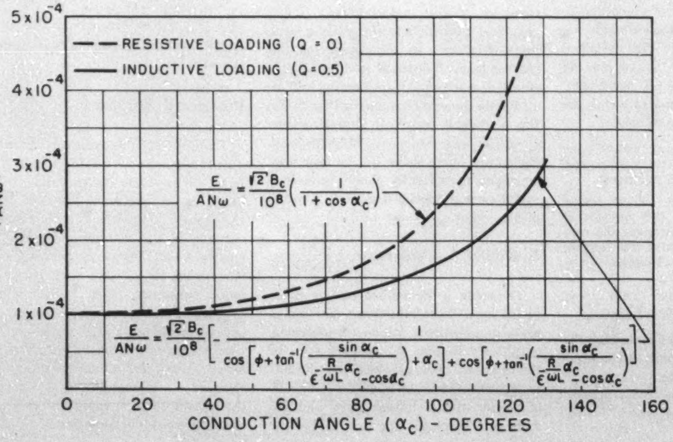

Fig. 15. Relation between E/ANω and conduction angle for reactors with Deltamax cores, $B_c=14{,}000$ gausses

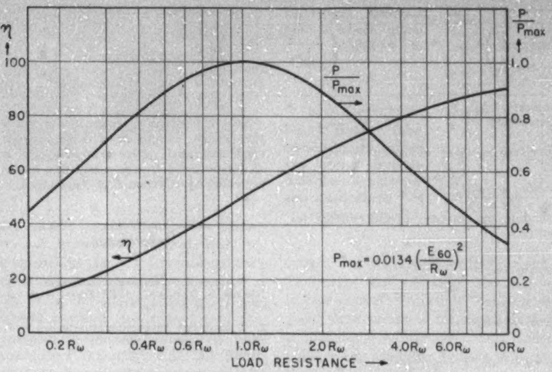

Fig. 16. Variation of power and efficiency with load

and multipliers for any given power output may be designed by the choice of an appropriate size of cores.

For a multiplier using three of the experimental reactors, the maximum power is $0.0134\times(52)^2/145=0.25$ watt compared with a measured power of 0.22 watt.

The experimental reactors used were already wound for a different purpose where the winding was occupying less than one-third of the available window area; consequently, the 0.25 watt does not represent the full power capability for the size of the core. An investigation of the power output must be based on a winding making full use of the window area of the experimental core which may be designed by following the procedure suggested. The maximum power output for such a winding is estimated as 0.7 watt.

For more power, more weight is required. The relationship between weight and power output may be deduced by applying equation 7 to reactors of different sizes. This was not investigated; however, it was observed that if n identical reactors of negligible winding reactances are connected in parallel and a voltage is applied, the conduction angle is the same as that for a single reactor having the same applied voltage, and the combination is equivalent to a single reactor having a winding resistance equal to R_w/n. Knowing this, and making use of equation 7, it may be concluded that the maximum power output for a multiplier having n identical reactors per branch is n times greater than that of a multiplier using a single reactor per branch, thus the power may be increased linearly as the weight.

Conclusions

The output of the multiplier may be considered as the sum of the outputs of three independent basic circuits. For any of the basic circuits, the critical voltage at which firing takes place is a characteristic of the reactor unaffected by the load conditions while for voltages higher than this value, the presence of the inductance in the load increases the conduction angle, thus making the reactor more sensitive to changes in voltage. The addition of inductance also improves the output wave shape which may be made approximately sinusoidal if enough inductance is added. However, the addition of inductance in series with the load will decrease the amplitude of the output, thus a compromise between power output and wave shape must be made. Following the design procedure outlined, frequency multipliers for any desired power ratings and efficiency may be built.

Appendix I. Relationship Between Applied Voltage and Conduction Angle

The differential equation describing the operation of the basic circuit of Fig. 4 in the presaturation region is

$$N\frac{d\Phi}{dt}\times10^{-8}+L_e\frac{di}{dt}+Ri=\sqrt{2}E\sin\omega t$$

Neglecting the $Ri+L_e di/dt$ drop, the differential equation reduces to

$$N\frac{d\Phi}{dt}\times10^{-8}=\sqrt{2}E\sin\omega t$$

Since $d\Phi=Ad\beta$

$$d\beta=\frac{\sqrt{2}E\times10^8}{AN}\sin\omega t$$

Integrating

$$\beta=K_t+\frac{\sqrt{2}E\times10^8}{AN\omega}\int_{t_1}^{t}\sin\omega t d\omega t$$

The foregoing equation simply says that the instantaneous value of the flux density is equal to the initial flux density plus a varying flux density proportional to the volt-time area of the applied voltage.

Case of Resistive Loading

For this case, the extinction is at an angle of π radians, as shown in Fig. 8, thus the angle at which the voltage cycle beginning at $\omega t=0$ starts to contribute the volt-time area necessary to raise the flux is at $\omega t=0$.

Letting $K_t=-B_c$, then

$$\beta=-B_c+\frac{\sqrt{2}E\times10^8}{AN\omega}\int_0^{\omega t}\sin\omega t d\omega t$$

At the instant of firing $\beta=+B_c$ and $\omega t=\alpha_f$.

$$B_c=-B_c+\frac{\sqrt{2}E\times10^8}{AN\omega}\int_0^{\alpha_f}\sin\omega t d\omega t$$

$$=-B_c+\frac{\sqrt{2}E\times10^8}{AN\omega}(1-\cos\alpha_f)$$

Solving for E yields

$$E=\frac{\sqrt{2}AB_cN\omega}{10^8}\left(\frac{1}{1-\cos\alpha_f}\right)$$

Since $\alpha_f=\pi-\alpha_c$

$$E=\frac{\sqrt{2}AB_cN\omega}{10^8}\left(\frac{1}{1+\cos\alpha_c}\right) \qquad (8)$$

Case of Inductive Loading

Because of the lagging effect introduced by the inductance, the current continues to flow beyond the point where the supply voltage drops to zero at the end of the positive half-cycle. Thus, the angle at which the voltage cycle beginning at $\omega t=0$ starts to contribute the volt-time area necessary to raise the flux is at the angle of $\alpha_n=\alpha_f+\alpha_c-\pi$, as shown in Fig. 13.

Letting $K_t=-B_c$, then

$$\beta=-B_c+\frac{\sqrt{2}E\times10^8}{AN\omega}\int_{\alpha_f+\alpha_c-\pi}^{\alpha_f}\sin\omega t d\omega t$$

At the instant of firing $\beta=+B_c$ and $\omega t=\alpha_f$. Therefore

$$B_c=-B_c+\frac{\sqrt{2}E\times10^8}{AN\omega}\int_{\alpha_f+\alpha_c-\pi}^{\alpha_f}\sin\omega t d\omega t$$

$$=-B_c-\frac{\sqrt{2}E\times10^8}{AN\omega}\times[\cos(\alpha_f+\alpha_c)+\cos\alpha_f]$$

Solving for E yields

$$E=\frac{\sqrt{2}AB_cN\omega}{10^8}\left(-\frac{1}{\cos(\alpha_f+\alpha_c)+\cos\alpha_f}\right)$$

Substituting for the value of α_f in terms of α_c deduced in Appendix II gives

$$E=\frac{\sqrt{2}AB_cN\omega}{10^8}\left[-\frac{1}{\cos\left[\phi+\tan^{-1}\left(\dfrac{\sin\alpha_c}{\epsilon^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)+\alpha_c\right]+\cos\left[\phi+\tan^{-1}\left(\dfrac{\sin\alpha_c}{\epsilon^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)\right]}\right] \quad (9)$$

For any fixed value of $\omega L/R$ the foregoing equation relates the rms applied volts to the conduction angle.

Appendix II. Relationship Between Conduction Angle and Current for the Case of Inductive Loading

The differential equation describing the operation of the basic circuit of Fig. 4 at saturation is

$$L\frac{di}{dt}+Ri=\sqrt{2}E\sin\omega t$$

Solving this equation and substituting the initial condition $i=0$ at $\omega t=\alpha_f$, the expression deduced for the current is

$$i=\frac{\sqrt{2}E}{(R^2+\omega^2L^2)^{1/2}}\times\left(\sin(\omega t-\phi)-\sin(\alpha_f-\phi)\epsilon^{-\frac{R}{\omega L}\alpha_c(\omega t-\alpha_f)}\right)$$

Substituting the second boundary condition $i=0$ at $\omega t=\alpha_f+\alpha_c$, shown in Fig. 13, in the foregoing equation gives

$$\sin[\alpha_c+(\alpha_f-\phi)]=\sin(\alpha_f-\phi)\epsilon^{-\frac{R}{\omega L}\alpha_c}$$

Expanding

$$\sin\alpha_c\cos(\alpha_f-\phi)+\cos\alpha_c\sin(\alpha_f-\phi)=\sin(\alpha_f-\phi)\epsilon^{-\frac{R}{\omega L}\alpha_c}$$

Dividing by $\cos(\alpha_f-\phi)$ and solving for $\tan(\alpha_f-\phi)$

$$\tan(\alpha_f-\phi)=\frac{\sin\alpha_c}{\epsilon^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}$$

From which,

$$\alpha_f=\phi+\tan^{-1}\left(\frac{\sin\alpha_c}{\epsilon^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)$$

This equation relates the firing angle to the conduction angle for any value of $Q=\omega L/R$.

Substituting α_f in the equation for current gives

$$i=\frac{\sqrt{2}E}{(R^2+\omega^2L^2)^{\frac{1}{2}}}\times\left[\sin(\omega t-\phi)-\sin\tan^{-1}\left(\frac{\sin\alpha_c}{\epsilon^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)\epsilon^{-\frac{R}{\omega L}\left[\omega t-\phi-\tan^{-1}\left(\frac{\sin\alpha_c}{\epsilon^{-\frac{R}{\omega L}\alpha_c}-\cos\alpha_c}\right)\right]}\right] \quad (10)$$

This equation is a general solution for the current corresponding to any given conduction angle where the value of E is also determined by the conduction angles expressed by equation 2 of Appendix I.

Properties of Silicon Power Rectifiers

E. F. LOSCO
NONMEMBER AIEE

THE STATIC electrical properties of small-area silicon *P-N* junction rectifiers prepared by the alloy fusion process have been described by Pearson and Sawyer[1] in 1952. Since that time rectifiers of the same type and having about the same *P-N* junction area (in the order of 0.0005 to 0.001 square centimeter (cm)) have become commercially available. The development of these rectifiers confirms theoretical expectations as to the superior electrical properties of silicon over germanium for semiconductor devices. These superior properties, which include extremely low reverse currents, high rectification ratios, and the ability to operate successfully at high ambient temperatures, are attributed to the wider energy gap in silicon (1.15 electron volts) as compared to germanium (0.75 electron volt).

Because the silicon rectifiers now available commercially are quite small in *P-N* junction area, they are necessarily limited to applications involving relatively low-level currents of 30 to 50 milliamperes (ma). The rms power outputs of these units, when used as single-phase, half-wave rectifiers with resistive load, are confined to 1 watt or less. It is well recognized therefore that the development of silicon rectifiers capable of handling several watts, or even several hundred watts of rectified power, would represent an important forward advance and open up many new power applications.

This paper is concerned with a description of some experimental silicon rectifiers capable of handling power outputs in the order of 500 to 1,200 watts. Both static and dynamic electrical properties to be described indicate that it is entirely feasible to realize such high-power handling ability for relatively large area (0.05 square cm) *P-N* junction silicon rectifiers prepared by the alloy fusion process.

Preparation of Silicon Power Rectifiers

The silicon power rectifiers have a junction area of approximately 0.05 square cm, or about 50 times the junction area of familiar commercially available units. The junctions are prepared by the alloy fusion process employing *N*-

type single crystal silicon. The silicon crystals, grown from the melt with the long axis in the [111] crystallographic direction, have electrical resistivity in the order of 1 to 5 ohm-cm. While several elements in Group III of the Periodic System have been employed for fusing the *P-N* junction, it has been found that aluminum is the most practical *P*-type impurity element to use. The melting point of aluminum, 660 degrees centigrade (C), is very convenient for alloy fusion. In addition, the low vapor pressure of aluminum at temperatures considerably above its melting point permits the fusion operation to be carried out without difficulty either in vacuum or inert gas atmospheres.

As illustrated schematically in Fig. 1, the rectifiers are assembled with suitable anode and cathode terminals which protect the brittle silicon wafer from damage during handling and permit easy assembly of electrical connections. Also illustrated in Fig. 1 is the method of encapsulation in a cylindrical copper heat exchanger having vertical fins arranged symmetrically around its outside periphery. The rectifier is mounted at the base of a blind cylindrical hole within the copper radiator, which serves also as one electrode of the rectifying cell. The other electrode is a wire lead emerging from the top of the radiator through a metal-to-glass bushing, which hermetically seals the rectifier. A suitable potting agent fills the cavity between rectifier and top of the heat exchanger, and electrically insulates the rectifier terminals. The completely assembled unit, shown in Fig. 1, is 1 inch in outside diameter and about 1 inch high.

D-C Characteristics at Room Temperature

The d-c reverse and forward characteristics of a 0.05 cm² fused *P-N* junction silicon rectifier is compared in Fig. 2 with those of a similar but very small area, 0.0009-cm² fused *P-N* junction unit. It will be noticed that the small area unit has very much lower leakage current. At 1 volt, for example, the leakage current is only slightly over 10^{-9} ampere. The larger area power rectifier has a leakage current of about 10^{-6} ampere or about three orders of magnitude higher at the same voltage level. At higher voltages this difference persists with not much change in the slopes of the two curves until reverse voltage breakdown is approached.

The reason for the higher leakage currents observed in the large-area rectifiers is not entirely clear. It is suspected, however, that the presence of shunts around the junction periphery may be responsible. The longer periphery and the greater chance of incomplete removal of shunts by chemical etching following the fusion operation suggests this possibility. Recent unpublished data on the effectiveness of various etchants on reducing the surface recombination velocity on germanium rectifiers indicates that surface preparation of the single crystal wafer is of extreme importance. This, no doubt, is also true in the case of silicon units and it is expected that future developments in this field will materially reduce leakage currents.

Neither the small- nor the large-area silicon rectifiers in Fig. 2 display a true reverse saturation current which would be expected from the theoretical current voltage relationship given by

$$I = I_0[\exp(qV/kT) - 1]$$

where

I = current, amperes per cm²
I_0 = a constant determined by silicon properties (such as lifetime of minority carriers, mobility, and resistivity)
q = electronic charge
V = voltage across the junction (plus for forward and minus for reverse currents)
k = Boltzmann's constant
T = absolute temperature

The reason for lack of current saturation in the reverse direction has been attributed to the low lifetime of minority current carriers in silicon. According to McAfee and Pearson,[2] working on junctions grown from the melt, the saturation current due to the minority carriers' diffusing into the space charge region is less than the reverse current due to carriers generated by traps within the space charge region, the trap reverse current being proportional to the width of the space charge region. Pearson and Sawyer[1] later extended this work and indicated lack of saturation also in small-area fused junctions.

Since the large-area fused junctions display similar reverse characteristics, it appears that improvement in this direction must come from the preparation of more nearly perfect single-crystal silicon having higher lifetimes, in the order of 100 to 300 microseconds instead of the at present available 10 to 50 microseconds. Occasionally, fused junction silicon rectifiers having reasonably good reverse saturation currents are prepared. This is more common in small-area rather than in large-area junctions. In such cases it is felt that a portion of the silicon ingot from which the crystal was prepared was exceptionally free of lattice imperfections.

Another interesting difference between the reverse d-c characteristics of small- and large-area fused junction silicon

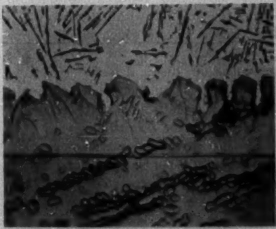

Fig. 3. Fused P-N junction in N-type silicon at 500 times magnification. Horizontal line is P-N junction separating original N-type silicon (bottom) from recrystallized P-type silicon. Aluminum-silicon eutectic is above recrystallized silicon. Lineage defects are evident within the silicon

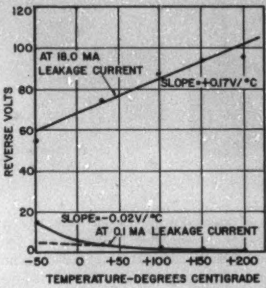
Fig. 5 (right). Effect of temperature on d-c reverse voltage characteristics at two levels of leakage currents



rectifiers is the sharpness of the breakdown voltage. The small area junctions have a sharp knee beyond which the voltage remains essentially constant over several orders of magnitude of reverse current. The larger area junctions, on the other hand, do not show a sharp breakdown but display a more gradual bend in the curve which is often referred to as a "soft knee." The softness varies somewhat from unit to unit and is often improved by chemical etching of the junction's periphery. Etching, however, does not completely overcome softness.

One possible reason for the inability to realize sharp breakdown voltages in large-area fused junctions may be associated with presence of imperfections in the silicon single crystal. A photomicrograph of a cross-sectioned silicon rectifier, 0.05 cm² in junction area, is illustrated in Fig. 3 at 500 times magnification. The original *N*-type silicon crystal, at the bottom of the photomicrograph, is seen to have numerous lattice defects believed to be lineage (exaggerated in size as a result of chemical etching). These defects pass through the *P-N* junction (which appears as a horizontal line) and continue to develop above the junction within the recrystallized P-type silicon, which has the same crystal orientation as the *N*-type. The presence of these defects, especially along the *P-N* junction plane no doubt prevent full realization of theoretically expected junction properties.

The d-c forward characteristics of the small-area rectifier indicates a forward current of 0.1 ampere at 1 volt. This corresponds to a current density of 110 amperes per cm². The rectification ratio at 1 volt is about 100,000,000, reflecting the very low leakage currents obtainable in small *P-N* junctions. The slope of the forward characteristic curve, however, increases relatively fast above about 1 volt. This appears to be characteristic of small-area silicon rectifiers.

The larger area fused junction silicon rectifiers have better forward characteristics than the smaller area units. At 1 volt, for example, the forward current is 10 amperes, which corresponds to a current density of 200 amperes per cm² for the 0.05-cm² area. In addition, the slope of the forward characteristic curve does not increase as rapidly over 1 volt as does that for the small-area junction. This is very desirable since the bulk of the heat developed in the junction results from the forward rather than the reverse characteristics. For power applications in which the dissipation of heat becomes a serious problem, the ability to realize low forward voltage drops is quite important. The large-area units also display a fairly high rectification ratio. Fig. 2 indicates a rectification ratio of about 5,900,000 at 1 volt. Values of this order can be realized in the 0.05-cm² *P-N* junctions, despite the relatively high reverse leakage, because the forward current density at 1 volt is improved considerably.

D-C Characteristics as Affected by Temperature

Temperature affects the reverse leakage of the 0.05-cm² silicon rectifiers very appreciably. This is shown graphically in Fig. 4 in which the d-c characteristics of a representative rectifier at −50, 28, 100, 150, and 200 C are plotted with the use of log-log scale. At low values of voltage, it is seen that leakage current increases as test temperature increases. It is also evident that the slopes of the reverse curves do not change markedly as test temperature is changed. When the applied voltage is sufficiently high, so that breakdown conditions are approached, the curves cross and leakage values become lower, the higher the test temperature. This effect has been previously described for small-area silicon junctions.[1]

Fig. 5 illustrates graphically the magnitude of reverse voltage change as affected by temperature at relatively high and low values of leakage currents. At an arbitrary leakage of 18 ma (beyond the knee of the current versus voltage curves in Fig. 4) the reverse voltage increases about 0.17 volts per C rise in temperature. At 0.1 ma leakage current, the voltage versus temperature curve has a negative slope and the voltage decreases at the rate of 0.02 volts per C over the straight-line portion of the curve. The magnitude of these changes may vary from unit to unit; the values given are therefore indicative of the trend for the 0.05-cm² area junctions described.

Fig. 4 also illustrates the effect of temperature on forward d-c characteristics. In this case, the effect is straightforward in that the forward voltage drop is lower, the higher the test temperature. At low values of forward current, temperature changes result in larger differences in forward drop then at high values of forward current. For a forward drop

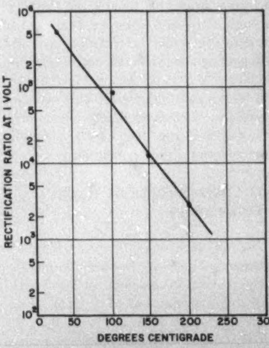


Fig. 6. Rectification ratio at 1 volt as affected by temperature

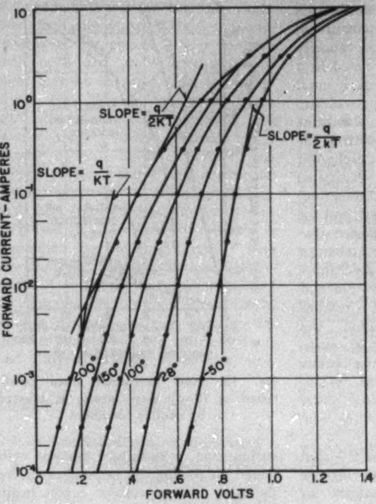

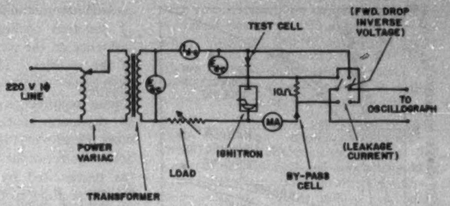

Fig. 7 (left). Approach of forward characteristics of power rectifiers to the current-voltage expression, $I = I_0$ [exp $(qV/kT)-1$], at various temperatures

Fig. 8 (above). Single-phase half-wave circuit diagram for power tests

of 0.5 volt for example, the forward current changes from 4.5×10^{-5} amperes at −50 C to 2×10^{-1} amperes at 200 C, a change of almost four orders of magnitude. At 1 volt, the corresponding change is from 1.5 to 3 amperes, or less than one order of magnitude.

The effect of temperature on rectification ratio for the application of 1 volt in both the forward and reverse directions is indicated in Fig. 6 for a typical 0.05-cm² area silicon rectifier. At room temperature, the forward to reverse current ratio is in the order of 500,000. This value decreases to 13,000 at 150 C and to 3,000 at 200 C. The increase in leakage current is primarily responsible for the drop in rectification ratio. Rectification ratios much higher than these, in the order of 6,000,000 at room temperature have been obtained as was previously shown in Fig. 2. Variations in the slope of the curve for rectification ratio as temperature is increased have also been noted. Uniformity of properties, in this respect, leave something to be desired. It is felt, however, that spread of results for the most part is dependent on material uniformity and fusion techniques. Improvements in the latter are expected materially to raise average rectification ratios.

It has been found that the current-voltage expression previously indicated is correct for forward currents of small area silicon *P-N* junctions. Fig. 7 illustrates the closeness of approach to this expression for the 0.05-cm² junctions at various temperatures. If close agreement is expected, then a plot of the forward current on a logarithmic scale versus forward voltage on an arithmetic scale should yield curves the straight-line portions of which have slopes corresponding to q/kT. It is apparent from Fig. 7 that at high temperatures, 200 C, there are two straight-line portions to the curve. One of these, which occurs at relatively low voltages (up to about 0.15 volt), has a slope which corresponds to q/kT as predicted. The other, occurring at higher voltages (0.2 to 0.5 volt), has a slope which corresponds to $q/2kT$.

At very low temperatures, −50 C, the straight-line portion of the curve falls in the range of 0.7 to 0.9 volt and its slope corresponds to $q/2kT$. It is possible that extension of this curve to lower values of voltages would also show a straight-line portion with slope q/kT. For intermediate temperatures, the straight-line portion of the curves has slopes which lie between q/kT and $q/2kT$ for the voltage range investigated. Here again it might be expected that the forward characteristics would follow the current-voltage expression at lower values of voltage.

A-C Characteristics

The a-c power tests carried out on the 0.05-cm² area silicon rectifiers involved 60-cycle single-phase half-wave circuits with resistive loads. The test circuit is illustrated in Fig. 8. The current-carrying ability of the encapsulated rectifiers was determined by noting how the peak values of forward voltage drop and leakage current varied as the load current was increased. This was done both for the case of natural convection air cooling and for the case of forced convection of air over the external fins of the copper heat exchanger. As the tests progressed, measurements were taken of the temperature of the heat exchanger about $^1/_{16}$ inch below the base terminal of the rectifier.

Results obtained for a rectifier operated at a peak inverse voltage of 100 volts are shown in Fig. 9. For natural air convection cooling, the forward drop and leakage curves vary almost linearly with load current until the latter exceeds a 5- to 6-ampere average. At 6 amperes, the leakage current has reached a value of 10 ma and is rising sharply, more so than the forward drop. It appears, in fact, that continued increase in the load current much beyond 7 amperes, at which point the leakage current is about 20 ma, would result in a runaway condition that would lead to failure of the rectifier. Therefore, for these particular conditions the silicon power rectifier can safely handle a load current of 6.5 amperes average at a 100-volt peak inverse. This corresponds to 10.2 amperes rms which, for the 0.05-cm² area junction, indicates a current density of 200 amperes rms per cm². The rms power output for natural air cooling,

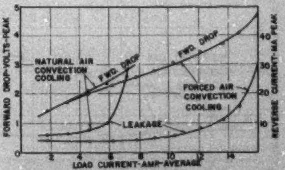

Fig. 9. A-c forward and reverse characteristics when power tested at 100-volt peak inverse for two methods of cooling

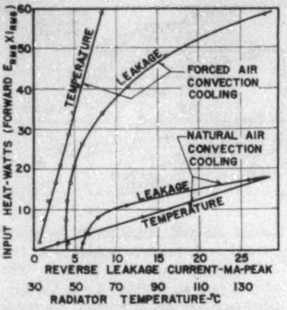

Fig. 10. Heat dissipation when power tested at 100-volt peak inverse as affected by cooling conditions

then, is $I_{rms} \times E_{rms} = 10.2 \times 50$, or 510 watts. The d-c power output is 6.5×32, or 207 watts.

For forced air convection cooling, the slope of the forward drop curve is somewhat lower than before and remains nearly linear until a load current in the neighborhood of a 15-ampere average is reached. The peak leakage current is reduced considerably, as would be expected, by air cooling. Its initial value is appreciably reduced, the curve having essentially a zero slope until quite high values of load current are reached. To reach a 20-ma peak leakage current, the load current must be more than doubled (from 7 amperes for natural air cooling to 15.25 amperes for forced air cooling). If a load current of 15 amperes average is taken as being a safe upper limit for forced air convection cooling, we can say that the encapsulated rectifier under these conditions can safely handle 24 amperes rms or about 480 amperes per cm². The rms power output of the rectifier then corresponds to 24×50 or 1,200 watts. The d-c power output in this case is 15×32 or 480 watts.

As illustrated in Fig. 9, the effectiveness of junction cooling has a pronounced influence on the power-handling capacity of the rectifier. The copper-finned heat exchanger used for the experimental silicon rectifiers is limited in its ability to dissipate heat. This is illustrated more clearly in Fig. 10 by plotting the actual power input to the heat exchanger (as represented by the heat dissipated by the rectifier in the forward direction) against the peak leakage current and the exchanger temperature. It is seen that the upper limit of the heat exchanger is approached when the curve for leakage current approaches zero slope. For natural air cooling, this condition is reached at about 20 watts' dissipation. For forced air cooling, it is over 60 watts. Peak leakage currents at these values are in the order of 25 to 30 ma. Thus, the previously mentioned output power ratings of the rectifier are on the conservative side.

It is also evident from Fig. 10 that heat exchanger temperatures as high as 140 C were reached for natural air cooling. At these temperatures, there was no indication of instability of the rectifier despite the relatively high leakage current. When forced air cooling is employed, the maximum exchanger temperature was only about 65 C. With more efficiently designed heat exchangers, and more effective cooling, more heat can be dissipated and advantage can be taken of the inherently high power-handling capacity of the rectifier.

Figs. 11 and 12 are the same types of plots shown in the previous two figures. The curves, however, are for a different encapsulated rectifier tested at 70-volt instead of 100-volt peak inverse. At the lower voltage higher forward currents can be handled since leakage currents are reduced. Thus, Fig. 11 shows that an 8.5-ampere average with natural air cooling and a 28-ampere average with forced air cooling can be applied before the peak leakage current curves begin to rise rapidly above 10 ma. These values correspond to current densities of 280 and 880 amperes rms per cm². The output power is 470 and 1,540 watts rms, or 190 and 625 watts d-c respectively. The heat dissipation, shown in Fig. 12, is in the order of 12 and 68 watts for the two cooling conditions. This corresponds to rectifier efficiencies of about 98 and 96 per cent respectively. It is also evident from Fig. 12 that the maximum temperature reached by the heat exchanger when natural air cooling was employed was 230 C. The temperature of the *P-N* rectifying junction itself is slightly higher than this, indicating the ability of silicon rectifiers to operate at theoretically predicted high ambient temperatures.

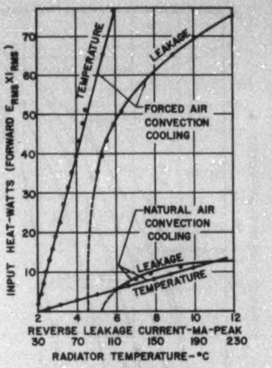

Fig. 12. Heat dissipation when power tested at 70-volt peak inverse as affected by cooling conditions

Numerous experimental silicon recti-

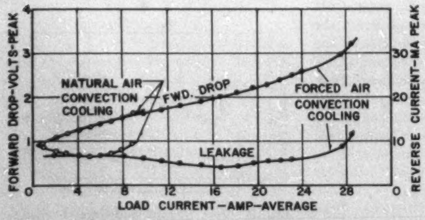

Fig. 11. A-c forward and reverse characteristics when power tested at 70-volt peak inverse for two methods of cooling

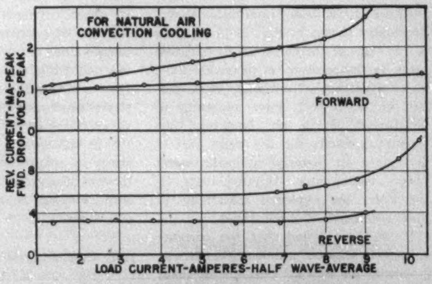

Fig. 13. Range of a-c forward and reverse characteristics for several rectifiers power tested at 50-volt peak inverse

fiers with 0.05-cm^2 junction area have been made and tested. The a-c characteristics so far presented were for two such units and are representative of what may be expected from individual units. Fig. 13, on the other hand, illustrates the range for forward and reverse characteristics obtained for a number of units tested at 50-volt peak inverse using natural air convection cooling only. Curves of this type along with those shown in Figs. 10 and 12 have been found to be extremely valuable in evaluating dynamic properties. Safe power ratings can thus be easily determined by noting the load current required to cause forward drop or, more likely, leakage current to rise sharply for different values of peak inverse voltage and different methods of junction cooling.

Summary and Conclusions

Experimental silicon rectifiers with a *P-N* junction area of approximately 0.05 cm^2 have been prepared by the alloy fusion process using *N*-type silicon and aluminum. These units are hermetically sealed in copper heat exchangers equipped with external vertical fins for either natural or forced air convection cooling. The units were subjected to both d-c and a-c tests over a series of temperatures varying from −50 to +230 C. From these tests the following conclusions are drawn.

D-C PROPERTIES

1. The rectifiers have quite low forward voltage drops, about 0.8 volt at 1 ampere, and can handle currents as high as 200 amperes d-c per cm^2 of junction area. In this respect, they compare favorably with very small area (0.001-cm^2) silicon-fused junction diodes.

2. They do not display a low saturation current, or a sharp breakdown voltage, as do very-small-area junctions. For many power applications, however, the leakage currents are low enough to be entirely adequate.

3. At room temperature, rectification ratios as high as 6,000,000 have been obtained at 1 volt. The ratio decreases as temperature increases, but usable values are obtained up to at least 200 C. A rise in leakage current is primarily responsible for the drop in rectification ratio with increasing temperature.

4. D-c breakdown voltages increase with increasing temperature. The forward d-c characteristics appear to follow the theoretical current-voltage expression, $I=I_0[\exp(qV/kT)-1]$ for low values of forward voltage which are obtained at high temperatures. For high voltages and low temperatures, the junctions follow more closely the expression $I=I_0[\exp(qV/2kT)-1]$.

A-C PROPERTIES

1. With only natural air convection cooling, the encapsulated rectifiers, arranged in a single-phase half-wave rectifier circuit with resistive load, are capable of handling a current density of 200 amperes rms per cm^2. They can deliver an output power in the order of 500 watts rms (207 watts d-c). For 100 volts peak inverse, this corresponds to a load current of a 6$^1/_2$-ampere average or 10.2 amperes rms.

2. With forced air convection cooling, the rectifier's power-handling ability is more than doubled. Current densities of 480 amperes rms per cm^2 and output power of over 1,200 watts rms (480 watts d-c) have been achieved. These values correspond with load currents of a 15-ampere average or 24 amperes rms at 100-volt peak inverse.

3. The silicon rectifiers themselves are capable of handling higher powers than those indicated. Power is limited now by the relatively low efficiency of the heat exchanger being used. With natural air convection cooling the upper limit of heat dissipation of the heat exchanger is in the order of 20 watts. For forced air convection cooling, heat dissipation is increased to the order of 70 watts.

4. Silicon rectifiers have been successfully operated with the use of natural air convection cooling with heat exchanger temperatures up to 230 C and with *P-N* junction temperatures somewhat higher than 230 C.

Junction Transistors Used as Switches

R. L. BRIGHT
ASSOCIATE MEMBER AIEE

MUCH literature has been devoted to the use of junction transistors as linear amplifiers but there has been very little information presented on the signal properties of these devices. As large signal devices, transistors have unique characteristics which enable them to perform many functions which were impossible with previously known devices. It is the purpose of this paper to point out some of these characteristics and to give a few illustrative applications.

The characteristics of a NPN fused junction transistor will be introduced by considering its behavior in the circuit shown in Fig. 1(A). The d-c volt-ampere characteristics for the input and output terminals are shown in Figs. 1(B) and (C). The curve in (B) shows that the input circuit looks much the same as a simple diode; the base current is very small if the base voltage is negative and becomes relatively large as the base voltage is made positive. The curve of (C) shows that, if the input is reversed biased 1/10th volt or more so that a small negative base current flows, then the load current in (C) will be very small and the transistor is said to be cutoff *A*. If the input is open-circuited, the base current will be zero and the load current will increase to the value at *B*. As the base voltage is made more positive, the operating point will move through the so-called linear region *C*. If the base current is raised to the value of 30 milliamperes (ma), the operating point will be at *D* and a further increase in the base-driving current will have practically no effect on the load current. This condition of operation is defined as saturation and is characterized by a very small collector-to-emitter voltage drop.

If the driving voltage V_b is abruptly switched from a negative value to a positive value, high enough to ensure saturation, the output circuit will be switched from *A* where the load current is very small to *D* where the load current is large and the voltage drop V_{ce} is very small. Under this condition, the transistor behaves similarly to the polarized relay shown in Fig. 2.

High-Level Operation

One advantage of operating the transistor in this on-off manner rather than as a linear amplifier is that the transistor

R. L. BRIGHT is with the Westinghouse Electric Corporation, Pittsburgh, Pa.

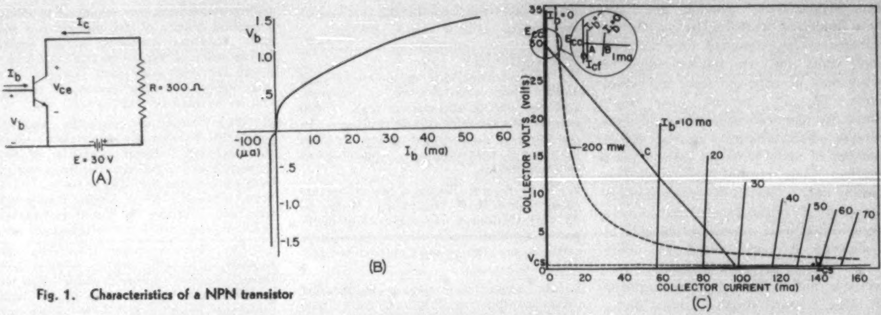

Fig. 1. Characteristics of a NPN transistor

power dissipation for such switching operation is only a small fraction of the peak load power that can be controlled whereas the dissipation is equal to or greater than the load power when linear operation is employed. For example, in the circuit of Fig. 1 the transistor dissipation at cutoff is equal to the base voltage times the base current plus the product of the collector current and voltage equals 1 volt × 2 microamperes + 30 volts × 30 microamperes = 0.9 megawatt (mw). At the saturation the transistor dissipation is $1.1\times30+0.25\times100=59$ mw and the load power is 3 watts. Thus, the load power is many times the dissipation. This fact means that the junction transistor is a very efficient device for controlling power. At present, it is limited to circuits having voltages on the order of 50 to 100 volts but, when used as a switch in such circuits, its efficiency is far higher than either gaseous or high vacuum tubes.

Note that the dissipation corresponding to C in Fig. 1 is 15 volts × 50 ma = 750 mw and is thus equal to about 1/4 of the peak load power. Since in practice the operating point must move continuously from A to D, the instantaneous power dissipation during this transition will be quite large and, therefore, the duration of the transition period must be small enough so that the total energy dissipated does not overheat the unit. This requirement is ordinarily easy to satisfy at frequencies up to 1,000 cycles per second; but at the high audio-frequencies the transition time often becomes an appreciable part of the cycle and this restriction may become serious. If the load current of Fig. 1 is assumed to have the wave shape shown in Fig. 3, the transition dissipation averaged over the entire cycle is P_L peak $(fT/3)$ where P_L = peak load power $=E^2/R$.

A typical value for T is 5 microseconds and thus, if the frequency f is 400 cycles per second, the average transition power dissipation is only $400.5\times10^{-6}/3=0.06$ per cent of the peak load power. However, at a frequency of 40 kc, it represents 6 per cent of the load power and may be the dominant term contributing to the total dissipation.

Referring again to Fig. 1(C), it may be seen that the amount of base current required to saturate the transistor depends upon the maximum load current. If the value of E/R is 100 ma, then a base current of 30 ma will be sufficient to ensure saturation. If E/R is 150 ma, a base current of at least 70 ma is necessary. At low-current densities, the relation between the minimum driving current required for saturation and the load current is nearly linear but, at the high-current densities often employed in power control circuits, this relationship becomes very complicated and must generally be determined experimentally. For high-gain units at low currents, the required base current may be as low as 1/100th of the load current while at high-current densities, this factor may be as high as 1/2. Even though the current gain at these high currents is only 1/2, the power gain (defined as the load power divided by the base input power) may be quite large. For example, if $E=30$ volts and $I_b=70$ ma, the curves of Fig. 1 show that $I_c=150$ ma, $V_b=1.7$, thus, $P_b=120$ mw. $P_L=4.5$ watts, so that the power gain equals 4,500/120 equals 37.5. The minimum required base drive P_b is completely determined if the maximum value I_c is specified and is independent of E if E/R is kept constant; therefore, the power gain at any particular load current is directly proportional to the source voltage E.

Fig. 4 shows a set of experimental curves giving the following quantities as a function of the load current I_L for the common emitter connection of Fig. 1. The curve of Fig. 4(A) shows the minimum base current required for saturation; (B) shows the base input power $P_b=V_bI_b$, the collector-emitter power $P_c=V_{ce}I_c$, and the total sum or total power dissipation P_c; and (C) shows the power gain per volt of the supply voltage $=I_L/P_b$. The per-cent power loss per volt of the supply voltage $=I_L/P_c$. (This is a measure of the over-all efficiency.)

Such curves furnish a convenient basis for a comparison between the various methods of connecting the transistor in the circuit. Curves of the total power dissipation P_c versus I_c are shown in Fig. 5 for the three basic connections: common emitter, common base, and common collector. These curves show that the common collector connection has the highest efficiency, but it has a disadvantage in that the base must be

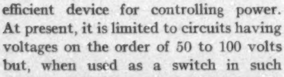

Fig. 2 (left). Equivalent polarized relay

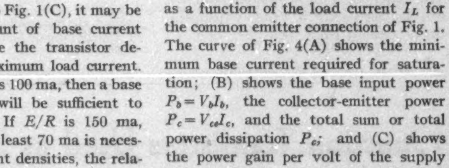

Fig. 3 (right). Wave shape showing transition interval

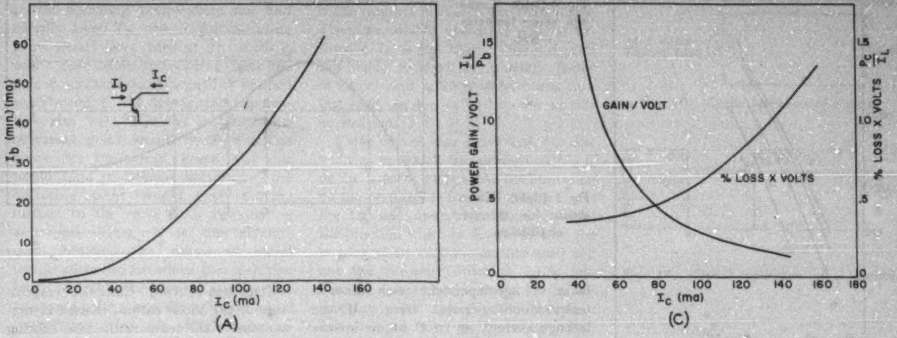

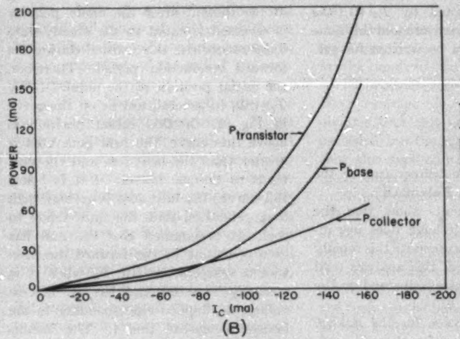

Fig. 4. High-level performance curves

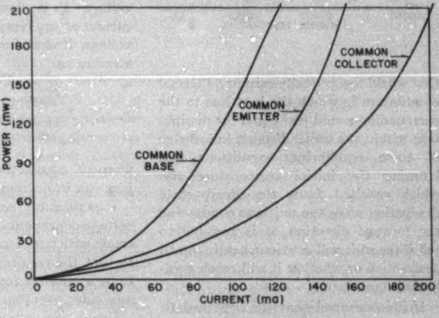

Fig. 5. Comparison of basic connections

negative with respect to the emitter at cutoff and, therefore, the input voltage at cutoff must be greater than the supply voltage E while during conduction it is only 1 to 2 volts. This is often awkward circuitwise and, therefore, the common emitter connection seems preferable for most high-power applications. For the benefit of those familiar with the ordinary transistor rating sheets, it should also be mentioned that in switching operation the breakdown potentials for the common emitter and common base connections are the same, it is only for linear operation that the voltage rating of the common emitter is less than that for common base.

Maximum Ratings

The power-handling capability of a given transistor can be determined if the cooling coefficient, the room temperature leakage, the ambient temperature, the duty cycle, and the amplitude and wave forms of the voltage that the unit is required to block are all known. The maximum load-handling capability may be limited by any one of the three following factors: the melting point of the terminals; the breakdown voltage of the junctions; or the phenomenon of thermal runaway. Thermal runaway is a consequence of the fact that the leakage current increases so rapidly with temperature that a condition may exist where a small rise in temperature results in an increase in leakage and, hence, an increase in power dissipation which is greater than the additional heat transfer to the surroundings resulting from this temperature rise. When this situation exists, the unit becomes hotter and hotter until it is destroyed. The melting point of the terminal is usually the limiting factor when the inverse voltages do not exceed about 10 volts. The junction breakdown voltage is a direct limitation only at very low ambient temperatures. For most applications, thermal runaway is the determining factor.

This thermal runaway criterion will be analyzed in detail for: a junction diode that has been conducting long enough to reach steady state whereupon the applied voltage is suddenly reversed; a junction diode in cyclic operation where the period is small compared to the thermal time constants; and a transistor in either cyclic or single on-off service.

A more complete statement of the first situation is: Assume that a diode is operating in a prescribed ambient temperature and has been conducting a specified constant current in the forward direction for a period long enough for the unit to reach thermal steady state. The polarity is then suddenly reversed and the unit is required to block a constant voltage. How does the maximum inverse voltage that can be applied without runaway depend upon the ambient temperature and the value of the dissipation that existed prior to the reversal?

The polarity of thermal runaway can be analyzed by determining the conditions

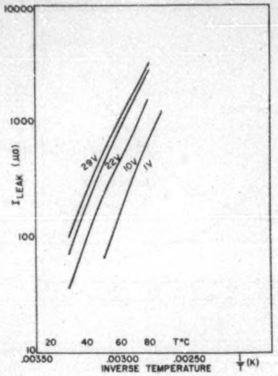

Fig. 6 (left). Leakage versus temperature

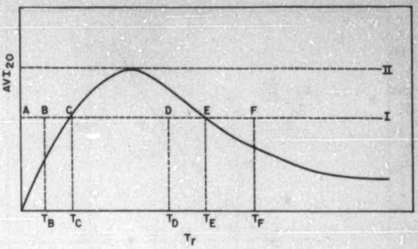

Fig. 7 (right). Condition for thermal equilibrium

that would theoretically exist at a thermal equilibrium in which the heat loss to the surrounding would just equal the dissipation within the unit. From a knowledge of these equilibrium conditions and knowing the initial temperature rise which resulted from the steady-state dissipation while the unit was conducting the forward direction, it is possible to tell if the unit will continue heating until destruction or whether it will reach equilibrium condition.

If it is assumed that the heat loss to the surroundings is directly proportional to the temperature rise above ambient, then a necessary condition for thermal equilibrium is that the temperature rise T_r, in degrees centigrade (C), is equal to the cooling coefficient A, in C per mw, times the dissipation within the unit. If the diode is blocking, this dissipation is equal to the inverse voltage times the leakage current and, since this leakage is a function of the temperature rise, its functional form must be investigated before the equilibrium can be computed.

Theoretically, the leakage current of a junction diode is an exponential function of the temperature of the form exp $(-8{,}350/T)$ for germanium and exp $(-12{,}900/T)$ for silicon and is independent of the applied inverse voltage above about 1/4 volt. In practice, this temperature dependence is followed quite closely at a low inverse voltage but the current is experimentally found to vary considerably with the applied voltage. In the remainder of this analysis, it will be assumed that this voltage-dependent component of the leakage current varies with temperature in the same manner as the theoretical constant component so that the leakage current can be written as a voltage-dependent term times a temperature-dependent term. If the leakage current at 20 C at an inverse voltage V is denoted by $I_{20}(V)$, the current at any temperature and this same voltage V can then be written for germanium as

$$I = I_{20}(V)\frac{\epsilon^{\frac{8{,}350}{-T(°K)}}}{\epsilon^{\frac{8{,}350}{-293}}}$$

where T equals the temperature of the junction in degrees Kelvin (K).

Experimental results show that the voltage-dependent leakage does not increase with temperature quite this rapidly so that the results of this analysis tend to be somewhat conservative and on the safe side; see Fig. 6.

Using this expression for the leakage current, the equation for thermal equilibrium can be written as

$$T_r = A\,VI = A\,VI_{20}(V)\frac{\epsilon^{\frac{8{,}350}{-T}}}{\epsilon^{\frac{8{,}350}{-293}}}$$

Letting

$$T = T_a + T_r + 273$$

where T_a = ambient temperature in C and rearranging

$$A\,VI_{20}(V) = \frac{T_r\,\epsilon^{\frac{8{,}350}{-293}}}{\epsilon^{\frac{-8{,}350}{273+T_a+T_r}}}$$

Thus, if the applied voltage and the ambient temperature are known, $I_{20}(V)$ and A can be measured and the equilibrium temperature rise T_r can be evaluated. A graph of $A\,VI_{20}(V)$ versus T_r for an ambient of 40 C is illustrated in Fig. 7.

This curve represents a locus of operating points at which the steady-state internally generated power is equal to the heat loss and, from it, the steady-state temperature rise that a diode would assume for any given value of inverse voltage can be read. Since the temperature of the diode cannot change instantaneously, the temperature rise existing at the instant after the diode polarity is reversed is equal to the steady-state temperature rise that existed during the forward conduction period. Therefore, the initial position of the point $(A\,VI_{20}, T_r)$ will, in general, not lie on the curve in Fig. 7. If this initial position is above this curve, the heat generated is greater than the heat loss and the unit tends to become hotter; if it is below this curve, the heat loss is greater than that generated and the unit tends to cool. It is assumed that the unit has been operating in the forward direction with a temperature rise T_B when it is suddenly reversed and has an inverse voltage V_1 applied corresponding to the horizontal dashed line I. The instantaneous operating point will then be at B which is above the steady-state curve and the unit will heat up until it reaches thermal equilibrium at a temperature T_C corresponding to point C.

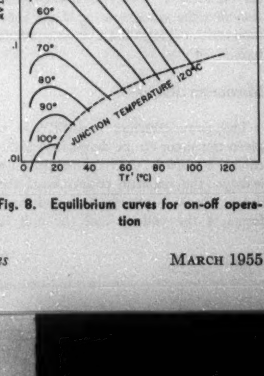

Fig. 8. Equilibrium curves for on-off operation

Vol.
Pt. 1
1955

If the operating temperature rise had initially been T_D, the initial operating point would have been at D, which is below the steady-state curve, and the unit would tend to cool until it reached equilibrium C. If the initial temperature rise were T_F, the instantaneous operating point would be F which is above the curve and, hence, the unit would tend to become hotter and the operating point would keep moving further to the right until the unit is destroyed. Thus, E is the dividing point between the values of initial temperature rise for which the operation tends toward the finite steady-state operating point C and the values of initial temperature rise for which runaway occurs. Note also that runaway will occur for all values of voltage which are higher than the value corresponding to line II regardless of the initial temperature rise.

Fig. 8 is a family of such curves for various ambient temperatures. If the inverse voltage V is specified and A and $I_{20}(V)$ are measured, it is possible to use this set of curves to determine the maximum forward dissipation that is permissible at any given ambient. Conversely, a test limit may be imposed in $I_{20}(V)$ that will insure that the unit will not run away with prescribed voltage, dissipation, and ambient temperature. For example, assume that it is desired to operate a diode at an ambient temperature of 60 C with a forward dissipation corresponding to a temperature rise of 40 C and an inverse voltage of 50 volts. The curves indicate that runaway will be avoided when the polarity reverses, if the product AVI_{20} is less than 0.088. Therefore, stable operation will be assured if I_{20} is less than $0.088/50A$, and this value reduced by a safety factor of 20 per cent or so may be taken as a test limit for diodes to be used in this application.

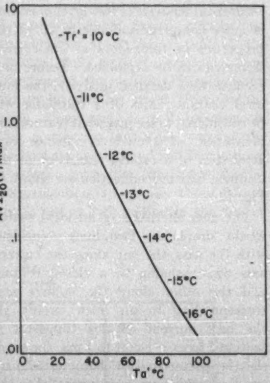

Fig. 9 Equilibrium curves for cyclic operation

These curves also show that, for low voltages at which the product AVI_{20} is on the order of 0.02 or less, the limitation on the permissible forward dissipation is the top-safe operating temperature of the junction which is determined by the melting point of the elements used and not the runaway criterion. For germanium devices having indium terminals (melting point 145 C), the maximum safe temperature is probably about 120 C.

The limitation imposed by the junction breakdown voltage is indirectly included in the analysis in that the value of $I_{20}(V)$ becomes very large as the breakdown voltage is approached. It is obvious that this voltage can never be exceeded, but the analysis has also shown that the maximum permissible voltage under high ambient conditions may be much less than the junction breakdown value.

The more common case in which the diode carries forward current for a fraction of each cycle and then sustains a reverse voltage for the remainder of the cycle can be handled by an extension of this analysis. Let

P_f = average power dissipation in the conducting or forward direction
P_i = average power dissipation in the inverse direction
A_f = cooling coefficient for the conduction period
A_i = cooling coefficient for the inverse period

The averaging is carried out over the entire cycle, e.g., the average forward power P_f is equal to the energy dissipated in the forward direction per cycle divided by the entire period. It is assumed that the frequency is high compared to the reciprocal of the thermal time constant of the diode.

The temperature rise is then given by

$$T_r = A_iP_i + A_fP_f$$

where

$$A_iP_i = A_i(I_iV_i)_{av} = A_iVI_{20}(V)_{av}\frac{\epsilon^{\frac{-8,350}{T_a+T_r+273}}}{\epsilon^{\frac{8,350}{-298}}}$$

$$AVI_{20}(V)_{av} = (T_r - A_fP_f)\frac{\epsilon^{\frac{8,350}{-298}}}{\epsilon^{\frac{-8,350}{T_a+T_r+273}}}$$

Substituting:

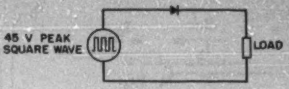

Fig. 10. Cyclic operation of a diode

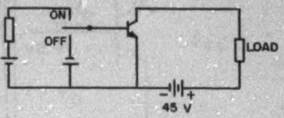

Fig. 11. On-off operation of a transistor

$$T_a' = T_a + A_fP_f$$
$$T_r' = T_r - A_fP_f$$

we obtain

$$A_iVI_{20}(V)_{av} = T_r'\frac{\epsilon^{\frac{8,350}{-298}}}{\epsilon^{\frac{-8,350}{T_a'+T_r'+273°}}}$$

This expression has the identical form as the corresponding expression for the steady-state solution of a diode with a constant inverse V, as given previously, where $VI_{20}(V)_{av}$ replaces $VI_{20}(V)$ and T_a' and T_r' replace T_a and T_r.

In other words, for cyclic operation, the temperature rise caused by the forward dissipation effects the reverse characteristic in exactly the same manner as an equivalent increase in the ambient. The general curves of Fig. 8 are thus applicable to this case also where the effective ambient temperature is the true ambient plus the temperature rise caused by the forward dissipation and the abscissa is the temperature rise above this effective ambient. Actually, for cyclic operation, the only point of interest on these curves is the value of the maximum voltage that can be sustained for any given effective ambient and this information can be replotted as the single curve of Fig. 9. As an example, consider the circuit shown in Fig. 10.

If the constants of the diode are $A_i = A_f = 0.15$ C per mw and $I_{20}(45) = 0.020$ ma, what is the maximum forward dissipation permissible at an ambient of 40 C? Since this is a 50-per-cent duty cycle

$$AVI_{20}(V)_{av} = 0.15\frac{(45)(0.020)}{2} = 0.0675$$

From Fig. 9, the highest effective ambient at which this value of $AVI_{20}(V)_{av}$ is permissible is 74 C. Hence, the maximum temperature rise caused by the forward dissipation must not exceed

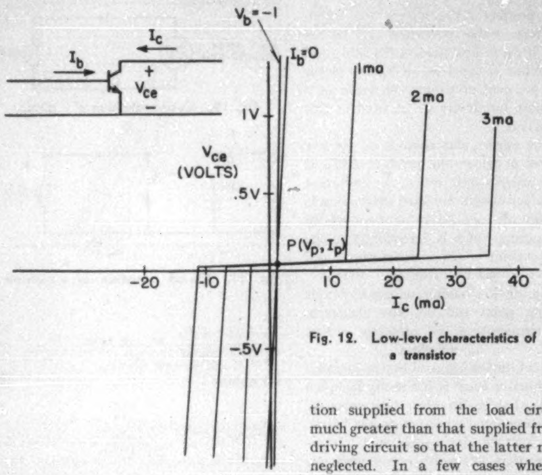

Fig. 12. Low-level characteristics of a transistor

74 to 40=34 degrees which corresponds to about 440 mw peak (again 50 per cent duty cycle). If the source voltage were sinusoidal, the form of solution would be the same except that value of $VI_{20}(V)_{av}$ would have to be found graphically from an oscilloscope.

In on-off duty, as in the first example, this diode would have a value of $AVI_{20}(V)=0.135$ at 45 volts and, from Fig. 8, could tolerate a forward temperature rise of 60 C at a 40-degree ambient, which corresponds to a 400-mw forward dissipation. Thus, the peak forward power in cyclic operation can safely exceed the maximum allowable in on-off operation so long as the period of oscillation is small compared to the thermal time constant. In general, a single on-off operation is the most severe for both diodes and transistors.

In extending this analysis to transistors used as switches, the only change required is that the power dissipation supplied by both the driving and load circuit must be taken into account. Thus, the temperature rise during conduction is A times the sum of these powers. Usually, the driving power is of the same order as the dissipation supplied from the load circuit and, hence, both must be computed.

In the cutoff conduction, the term $AVI_{20}(V)$ must be generalized to include a term $AV_dI_{20}(V_d)$ for the drive circuit plus a term $AV_1I_{20}(V_1)$ for the load circuit. In most cases, the load supply voltage is much higher than the driving cutoff voltage and the leakage dissipation supplied from the load circuit is much greater than that supplied from the driving circuit so that the latter may be neglected. In a few cases where the transistor is being used in the inverted connection and the saturation current of the emitter junction is very flat, this assumption may not be valid and both powers may have to be included.

As an example, for the circuit of Fig. 11, determine the maximum total forward dissipation permissible for a single on-off operation at an ambient of 40 C with a load supply voltage of 45 volts and a cutoff leakage current in the load circuit of 20 microamperes and a cutoff leakage current of 2 microamperes at 1.5 volts in the basic circuit at 20 C.

The total leakage power at 20 C is

$$1.5(0.002)+45(0.02)=0.9 \text{ mw}$$

Thus

$$AI_{20}(V)V=0.15+0.9=0.135$$

From Fig. 8, the maximum permissible forward power dissipation is

$$\frac{0.60 \text{ C}}{0.15 \text{ C per mw}}=400 \text{ mw}$$

Note the highest ambient temperature at which this transistor could sustain 45 volts can be found from either Fig. 8 or 9 to be 63 degrees and the maximum forward dissipation at this temperature is about

$$\frac{13.5 \text{ C}}{0.15}=90 \text{ mw}$$

Establishing ratings for transistors in class-A and B operation is more difficult. The same thermal equilibrium condition $T_r=AP$ still holds, but the temperature dependence of P can be very involved. The collector current, e.g., is I_e+I_{c0} where I_{c0} has the same type of exponential dependence previously given for the leakage current. Most amplifier circuits incorporate stabilizing resistors in series with the emitter so that a change in the quiescent current feeds a voltage change back to the base so as to change the emitter current; thus, the emitter current changes with temperature in a manner dependent upon the circuit used. Similarly, the collector voltage depends upon the total current and, hence, also varies in a complicated fashion with temperature. Therefore, the expression of P as a function of temperature depends upon the circuitry and no general runaway criterion can be given.

The ratings established here only guarantee that the transistor will not burn out at the upper temperature limits; they do not guarantee that circuits incorporating these transistors will operate satisfactorily. At high temperatures, the leakage currents may be an order of magnitude or more greater than at room temperature and the circuit must be designed to perform correctly even with this high leakage. For both transistors and diodes, it was the conducting dissipation and not the conducting current that was specified. The relation between dissipation and current may be obtained from curves of the type shown in Fig. 5.

Low-Level Operation

In addition to having much higher efficiencies than tubes, transistors also have the advantage that they can operate at much lower voltages: in many cases the transistor behaves as a nearly ideal switch down to potentials on the order of 100 microvolts. The theoretical analysis of low-level operation is quite complete and nearly all of the properties of transistors at low-current densities can be explained. Before proceeding to a detailed analysis, the low-level characteristics of a transistor will be considered to see just what features are of interest. The low-level collector characteristics of a typical transistor in the common emitter connection are shown in Fig. 12.

The characteristics of an ideal switch would simply be two lines coincident with the axis, the one along the current axis corresponding to a closed contact and the other along the voltage axis corresponding to an open circuit. If the base current of this transistor is switched from −1 volt to 1 ma, the small signal collector-emitter characteristics are two lines which are nearly parallel to the axis but which do not intersect at the

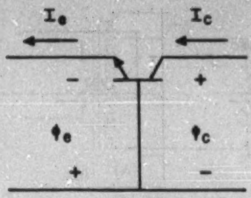

Fig. 13. General transistor equations

$$I_e = I_{e0}\frac{\left(\epsilon^{\frac{q\phi_e}{kT}}-1\right)-\alpha_i I_{c0}\left(\epsilon^{\frac{q\phi_c}{kT}}-1\right)}{1-\alpha_i\alpha_n}$$

$$I_c = \frac{+\alpha_n I_{e0}\left(\epsilon^{\frac{q\phi_e}{kT}}-1\right)-I_{c0}\left(\epsilon^{\frac{q\phi_c}{kT}}-1\right)}{1-\alpha_i\alpha_n}$$

$$\alpha_i I_{c0} = \alpha_n I_{e0}$$

where

α_n = current gain in the normal connection and is ordinarily between 0.90 and 0.999
α_i = current gain in the inverted connection and is ordinarily between 0.3 and 0.6, although it may be about 0.98 in special symmetrical units
I_{c0} = saturation current of the collector junction
I_{e0} = saturation current of the emitter junction

origin but rather at a point $P(I_p, V_p)$ in the first quadrant. In other words, the transistor is nearly equivalent to an ideal switch in series with a battery V_p and shunted by a current source I_p. This battery and current source impose a practical lower limitation on the power level of a load circuit which can be satisfactorily controlled by a transistor switch. The closer that this point P can be made to the origin, the lower the satisfactory operating level becomes. It was first found experimentally and later verified theoretically that, if the collector and emitter terminals were interchanged, the resulting characteristics had an intersection much closer to the origin than the normal connection. This connection has been termed the inverted connection and will be analyzed in detail. Since the effective alpha for the connection is typically about 0.5, its gain is not as high as that of the normal connection, but in many low-level circuits this is not of significant consequence.

The low-level operation of a fused junction transistor can be analyzed quite accurately by using the set of equations which were first given by Ebers and Moll.[1] These equations do not take into account any internal resistance drops, in that the potentials that appear are not the applied potentials but are the potentials across the junctions. For the moment, these internal resistance drops will be neglected and the potential across the junction is assumed to be the same as the applied potential.

Before presenting these general transistor equations, it is worth while to discuss the theoretical equation for the behavior of a fused junction diode which is

$$I = I_s\left(\epsilon^{\frac{qV}{kT}}-1\right)$$

where

q = charge of electron
k = Boltzmann's constant
T = absolute temperature, K
$\frac{kT}{q}$ = 26 microvolts at 20 C
I_s = constant

If V is made more than 1/10th volt negative, the exponential term becomes negligible with respect to unity and the leakage current theoretically remains constant at I_s up to the breakdown voltage. In practice, the leakage increases somewhat with voltage but many diodes approximate this theoretical behavior quite closely. This constant leakage current I_s is called the reverse saturation current of the diode; this has nothing to do with the conduction saturation previously discussed. In the forward direction, the current is nearly an exponential of the applied voltage. Note that the ratio of the forward-to-back currents at any particular voltage $\pm V$ is given by

$$\frac{I+}{I-} = \frac{\epsilon^{\frac{qV}{kT}}-1}{\epsilon^{-\frac{qV}{kT}}-1} = 55 \text{ at } \pm 0.1 \text{ volt}$$

and is independent of any of the properties of the semiconductor or the geometry and size of the unit. In other words, a unit having a low forward drop will have a high leakage and vice versa.

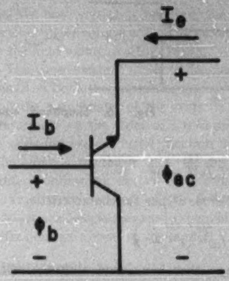

Fig. 14. Equations for the inverted connection

$$I_b = +I_{c0}\left(\epsilon^{\frac{q\phi_b}{kT}}-1\right)-(1-\alpha_n)I_e$$

$$I_e = I_{0e}^{\frac{+q\phi_b}{kT}}\left(\epsilon^{-\frac{q}{kT}\left(\phi_{ec}-\frac{kT}{q}\ln\alpha_n\right)}-1\right) = \left(\frac{1-\alpha_n}{\alpha_n}\right)I_0$$

where

$$I_0 = \frac{\alpha_n I_{c0}}{1-\alpha_i\alpha_n} = \frac{\alpha_i I_{c0}}{1-\alpha_i\alpha_n}$$

The corresponding theoretical equations for a transistor are given in Fig. 13. From the construction of a transistor it might be expected that it would behave as two diodes which react on one another and the similarity of the terms in these equations to that just given for a diode confirms this viewpoint.

As was mentioned, the most favorable connection for low-level operation is the inverted circuit shown in Fig. 14. The equations governing this connection can be derived from those previously given by using the relations: $\phi_b = \phi_c$, and $I_b = I_e - I_c$. With appropriate juggling, these expressions can be put in the forms given in Fig. 14.

By recognizing that an ideal diode has the characteristics $I = I_s[\epsilon^{(q\phi/kT)}-1]$, these equations may be interpreted as being equivalent to the characteristics of the circuit shown in Fig. 15, where diode D_1 has the characteristic

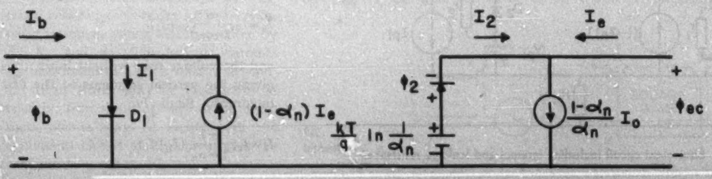

Fig. 15. Large signal equivalent circuit

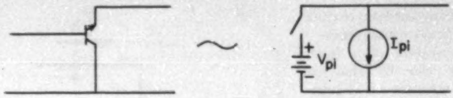

Fig. 16. Simplified equivalent circuit

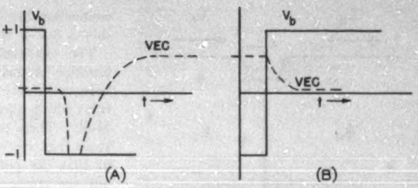

Fig. 18. Transient phenomena

$$I_1 = I_{c0}\left(\epsilon^{\frac{q\phi_b}{kT}} - 1\right)$$

and diode D_2 has the characteristic

$$I_2 = I_{e0}{}^{\frac{q\phi_b}{kT}}\left(\epsilon^{\frac{q\phi_2}{kT}} - 1\right)$$

The author has found this equivalent circuit extremely valuable in visualizing the behavior of switching transistors.

For example, it can be shown that the values of the battery and current source in the load circuit are equal to the co-ordinates of the common intersection point $P(I_{pi}, V_{pi})$ of the emitter-collector volt-ampere characteristics. To obtain an expression for the corresponding co-ordinates for the common emitter connection, it is only necessary to interchange the subscript i with the subscript n and I_{e0} with I_{c0}. Note that since I_0 is symmetrical in these terms, it remains invariant and the co-ordinates of P for the two connections become:

Inverted connection

$$\frac{1-\alpha_n}{\alpha_n}I_0, \ \frac{kT}{q}\ln\frac{1}{\alpha_n} = (I_{pi}, V_{pi})$$

Common emitter connection

$$\frac{1-\alpha_i}{\alpha_i}I_0, \ \frac{kT}{q}\ln\frac{1}{\alpha_i} = (I_{pn}, V_{pn})$$

For most commercial junction transistors, α_n is much nearer unity than α_i, typical values being $\alpha_n = 0.99$; $\alpha_i = 0.5$.

Equating the connection expressions for these values:

Inverted connection

$$\left(0.01\,I_0,\ 0.01\frac{kT}{q}\right)$$

Common emitter connection

$$\left(1.0\,I_0,\ 0.69\frac{kT}{q}\right)$$

This illustrates that the co-ordinates of the intersection P for the inverted connection may be orders of magnitude smaller than those for the common emitter. This fact has two very important consequences:

1. A transistor, when used in the inverted connection, will function at much lower load power levels than when used in the normal connection.
2. A transistor, when used in the inverted connection, has a room-temperature leakage current at cutoff which is an order of magnitude lower than that of the normal connection.

This second property has the important consequence that the value of $AVI_{20}(V)$ at any given voltage may be an order of magnitude less for the inverted than for the normal connection and, therefore, the inverted connection may be operated at a much higher temperature without runaway.

The switching function is closely associated with the properties of the diode D_2 which has the very interesting characteristic $I_2 = I_0 \exp(q\phi_b/kT)[\exp(q\phi_2/kt) - 1]$. Consequently, it behaves like an ideal diode. Its unique property is that the coefficient $I_s = I_0 \exp(q\phi_b/kT)$ can be varied by means of another electric potential ϕ_b. Thus, this coefficient can be made large during conduction and very small during cutoff. It is quite feasible for this diode to present a ration of front-to-back conductance on the order of 1,000,000 down to a few microvolts. In practice, the reduction of back leakage is limited by the voltage-sensitive component of the emitter leakage which can be represented by a resistance in parallel with the diode and which is ordinarily on the order of 1 megohm. In most low level applications, the base driving voltage is large compared to the current to be controlled and this diode D_2 can be thought of as an ideal switch controlled by the voltage ϕ_b.

Thus, if the base current is sufficient to hold the transistor saturated during the conduction period, a junction transistor having a square wave driving voltage impressed between the base and collector (the so-called inverted connection) is approximately equivalent to a switch in series with a battery and in parallel with a current source, as shown in Fig. 16.

Typical magnitudes are about 1 millivolt for V_{pi} and 1 microampere for I_{pi} at room temperature. V_{pi} varies somewhat with temperature but generally remains between 1/2 and 2 millivolts over the range of −65 to 100 C. I_{pi} increases exponentially with temperature at about 8 per cent per C.

The normal connection in which the square wave is applied between the base and emitter has a similar equivalent except that V_{pn} and I_{pn} are usually one to two orders of magnitude greater than V_{pi} and I_{pi}.

An analytical expression for the potential drop at any current is given by

$$\phi_{ec} = V_{pi} + \frac{kT}{q}\ln\frac{1+(1-\alpha_n)\dfrac{I_e - I_{pi}}{I_b + I_1}}{1-\dfrac{1-\alpha_i}{\alpha_i}\dfrac{I_c - I_{pi}}{I_c + I_1}}$$

where

$$I_1 = I_0\left(\frac{1-\alpha_i}{\alpha_i} + \frac{1-\alpha_n}{\alpha_n}\right)$$

This is, in fact, the equation for the entire family of curves of Fig. 12. When the denominator of the logarithm becomes zero

$$I_e = I_{pi}\frac{\alpha_i}{1-\alpha_i}(I_b + I_1)$$

and the voltage rises without limit, thus giving the vertical segments in the first quadrant. Similarly

$$I_e = I_{pi}\frac{-1}{1-\alpha_n}(I_b + I_1)$$

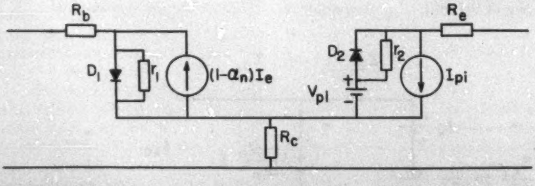

Fig. 17. Equivalent circuit including internal and leakage resistances

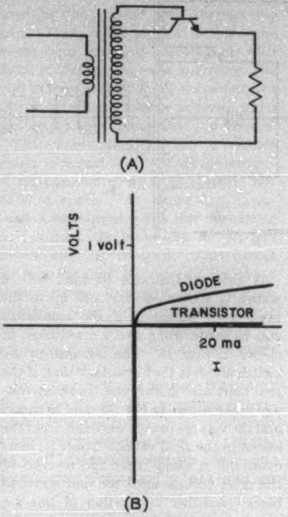

Fig. 19. Synchronous rectifier

corresponds to the vertical portions in the third quadrant. If the maximum value of $I_e - I_{pt}$ in the first quadrant is termed the maximum forward current and is denoted by the symbol $I_f = \alpha_i/(1-\alpha_i)$ $(I_b + I_1)$ and the maximum reverse current by $I_r = 1/(1-\alpha_n)$ $(I_b + I_1)$, then the expression for ϕ becomes simply

$$\phi_{ec} = V_{pt} + \frac{kT}{q} \ln \left(\frac{1 + \frac{I_e - I_{pt}}{I_f}}{1 - \frac{I_e - I_{pt}}{I_r}} \right)$$

The dynamic resistance $R_{dyn} = \phi_{ec}/I_e$ evaluated at the point $P(V_{pt}, I_{pt})$ is $(kT)/[q(I_b + I_1)]$ $(1-\alpha_i\alpha_n)/\alpha_i$ and this resistance may be added in series with the circuit of Fig. 16 to give a more accurate equivalent. Ordinarily, I_1 is completely negligible compared to I_b during the conduction period and hence, may be omitted from these equations. If $(1-\alpha_i\alpha_n)/\alpha_i = 1$ and $I_b = 10$ ma, then $R_{dyn} = 2.5$.

In practice, there are always some internal resistances in series with the transistor terminals which will be denoted by R_b, R_c, and R_e. The leakage currents are also found to have a voltage-dependent term which may be thought of as resulting from shunting resistances. Both these effects may be included in the equivalent circuit of Fig. 15 to give the configuration of Fig. 17.

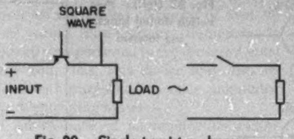

Fig. 20. Single-transistor chopper

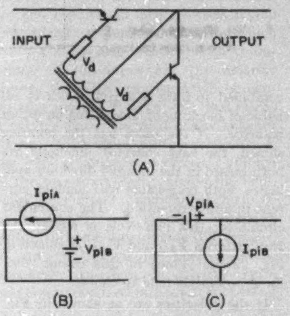

Fig. 21. Two-transistor chopper

R_b is usually quite appreciable, 50 to 200 ohms, and may vary by a factor of 4 from one unit to another of the same type. R_c and R_e are on the order of 1 ohm for fused junction units but R_c may be hundreds of ohms for grown junction types. Since R_e serves to couple the input and output circuits, grown junction units are generally not applicable in low-level circuits. R_1 and R_2 may be on the order of 0.1 to 10 megohms.

The transient behavior of junction transistors has been beautifully analyzed by J. L. Moll[3] and this work will not be repeated here. The usual manifestations of the transient phenomena in a low-level common emitter circuit are: If the unit is initially conducting with a very small voltage drop V_1 and the base potential is abruptly reversed, the collector emitter potential will remain unchanged for a short interval and will then suddenly drop to approximately the value of the applied base potential and then decay to its steady value; see Fig. 18(A). Similarly, if the unit has been cut off and the base voltage is reversed, the collector-emitter voltage will decay smoothly to the final value; see Fig. 18(B).

The time constant of these decays depends on both the transistor parameters and the magnitudes of the currents and are usually on the order of 1 to 5 microseconds for present fused junction units. The effect, depicted in Fig. 14, may be quite troublesome in low-level applications although several of the following circuits are designed so that these voltage spikes do not appear in the output.

Applications

A circuit which very nicely demonstrates the advantages to be gained through the use of transistors is the synchronous rectifier shown in Fig. 19. When the instantaneous polarities are as shown, the transistor is conducting in a common collector connection and can thus handle a large current and yet have the voltage drop across it very small. When the polarity reverses, the transistor blocks and only the small leakage current I_{pt} flows. This device thus avoids the severe inner dependence of the forward and back characteristics of a diode and can exhibit forward-to-back ratios of 100,000 down to 1 millivolt. As a consequence of the reduced leakage, this rectifier can operate at temperatures about 40 C hotter than a corresponding diode of the same material.

If this circuit is used as the self-saturating rectifier in a magnetic amplifier, the voltage that the load windings is required to sustain may be reduced to a fraction of 1 volt, thereby making practical the use of very small cores to yield an extremely sensitive amplifier having a high speed of response. The low-voltage characteristics of the transistor make possible the replacement of the input mechanical vibrators in low-level d-c amplifiers. One of several possible circuits is shown in Fig. 20.

If the transistor were an ideal switch, this circuit would be equivalent to the right-hand figure. Here, the input is alternately connected and disconnected to the output and, therefore, the output voltage is a rectangular wave that alternates between zero and the value of the input voltage. Actually, the transistor is not

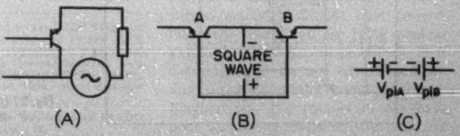

Fig. 22. Two-transistor a-c switch

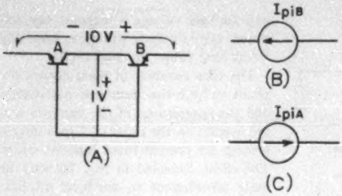

Fig. 23 (left). A-c switch during blocking interval

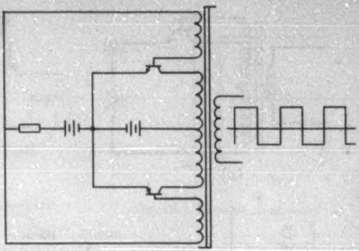

Fig. 26 (right). D-c to a-c converter

ideal, but is roughly equivalent to a battery: V_{pi} when conducting and a current source, I_{pi} when nonconducting. Thus, even if the input voltage is zero, a voltage of V_{pi} will appear at the output during the conducting half-cycle, and a voltage $I_{pi}R$ during cutoff. If this latter voltage is to be kept small, it means that the load resistance R must be small.

A much better modulator circuit is given in Fig. 21(A). First consider the behavior of this circuit with the input short-circuited. The two half-cycles can then be represented by the equivalent circuits of Figs. 21(B) and (C). The current sources are effectively short-circuited by the batteries during both halves of the cycle and the output alternates between V_{piA} and V_{piB}. If these two voltages are equal, the output is pure direct-current and contains no a-c component. Thus, as far as inverter operation is concerned, V_{piA} and V_{piB} tend to cancel.

An NPN transistor can block only if the base is more negative than both the collector and the emitter. Therefore, a transistor in the simple circuit described in the following cannot block an alternating source during the half-cycle when the polarity is as shown in Fig. 22(A). Fig. 22(B) shows how two transistors can be combined to form a switch which is capable of blocking or conducting on either polarity. If the wave has the polarity shown, the base collector junctions are both biased in the forward direction and, hence, both transistors will conduct current in either direction. The equivalent circuit for this half-cycle is merely the two batteries V_{piA} and V_{piB}, as shown in Fig. 22(C). Thus, in this circuit also, these potentials tend to cancel.

If the polarities are as shown in Fig. 23(A), both collector junctions are biased in the reverse direction. The emitter of transistor A is also negative with respect to the base and, hence, both junctions of A are biased backwards and the circuit is cut off. Similarly, if the controlled circuit potential reverses, transistor B has both junctions biased backwards and, hence, blocks the circuit. The equivalent circuit for the cutoff conditions is quite complicated, but if the controlled circuit potential is 1 volt or more and has the polarity shown, the equivalent circuit is approximately given by Fig. 23(B) and, similarly, for the opposite polarity by Fig. 23(C).

A chopper that can be used with a source of either polarity and up to the breakdown potential of the transistors can be made using two a-c switches, as shown in Fig. 24. The 2-transistor a-c switch also has the advantage that, if the two units are similar, the transient-voltage peaks shown in Fig. 24 tend to cancel and the voltage decays smoothly from the initial to the final value. There is, however, still a decay after the reversal of the drive voltage until the unit starts to block. Another application of this a-c switch is in the phase-sensitive detector or demodulator, as shown in Fig. 25.

The driving square wave establishes the phase reference. If the square wave polarity is as indicated, transistor switch B, will be conducting and transistor switch A will be cut off. Thus, the circuit will be completed, as shown by the dashed line; the direction of the current will depend upon the polarity of the source. On the other half-cycle, A will conduct and B will be cut off, thereby

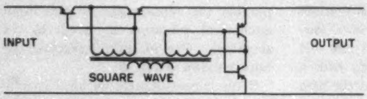

Fig. 24 (left). Four-transistor chopper

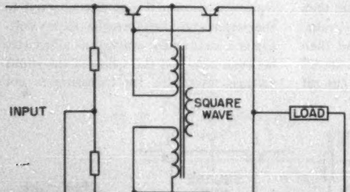

Fig. 25 (left). Four-transistor demodulator

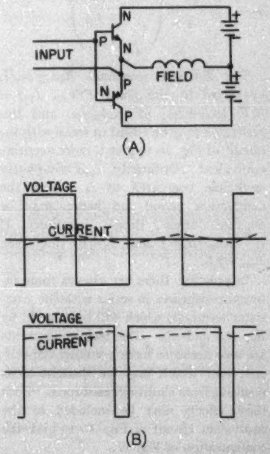

Fig. 27 (right). Transistorized field controller reversing the current path through the load. Thus, if the input is a sine wave whose zero crossings correspond with those of the square wave reference, the load voltage will be a full wave rectified sine wave whose polarity reverses when the input phase changes by 180 degrees.

This circuit requires a low impedance source to assure that the leakage current of the nonconducting transistor will not cause an appreciable voltage drop to appear at the output. If a low impedance load is used, the input and output terminals may be reversed. This circuit can also be used to measure the phase angle between the input and reference voltages. This demodulator is very linear from about 100 microvolts to 50 volts and is operable over a temperature range of −65 to +75 C.

By combining switching transistors and elements having rectangular hysteresis core materials, it is possible to achieve many novel results. For example, Fig. 26 shows a converter which produces a rectangular a-c output with an over-all conversion efficiency of over 90 per cent. The output frequency is directly proportional to the d-c input voltage and, thus, this device may also be used as a precision frequency modulator in telemetering systems.

An example of an application motor control system is the static field controller shown in Fig. 27(A). Here, advantage is taken of the fact that a transistor can conduct in either direction and can, therefore, perform functions which are not at present practical with thyratrons. If the input has the polarity shown, the NPN transistor will be conducting and the PNP cut off; this places a voltage across the field of the polarity shown. With the opposite polarity input, the PNP conducts and places a voltage of the opposite polarity across the field. Thus, this circuit functions similarly to a double-pole double-throw reversing switch with one outstanding difference—it can be thrown practically instantaneously. In effect, the polarity of the field can be reversed without ever opening the field circuit; thus, there will be no high-voltage surges and no discontinuities in the current. The average field current can be controlled by varying the ratio of the time that one polarity of voltage is applied to the time that the polarity is applied. Typical wave forms are shown in Fig. 27(B). If the frequency of these rectangular waves is high compared to the reciprocal of the time constant of the field, the field current will have very little ripple. This circuit can be held closed in either direction and can apply full forcing to the field in either direction. These applications serve to illustrate the great potentialities of using fused junction transistors as switches at both high- and very-low-power levels.

Transistor Demodulator for High-Performance Magnetic Amplifiers in A-C Servo Applications

R. O. DECKER
ASSOCIATE MEMBER AIEE

FULL-WAVE magnetic amplifiers are not efficiently controlled with a-c signals applied directly to the control windings because the circuit configurations necessary do not give sufficiently high gain. Half-wave magnetic amplifiers which can accept a-c signals directly have relatively low gain. The most sensitive, stable magnetic amplifiers require a d-c control current, but in many servo applications the servo amplifier must accept a phase-reversible alternating voltage and deliver an output that will reverse phase as the phase of the input signal reverses.

An ideal solution to the a-c input problem is obtained by inserting a phase-sensitive demodulator in series with the magnetic amplifier control windings. Such a demodulator however, must have good balance characteristics over a wide temperature range, and its transfer curve must be linear even at low voltage levels. To maintain the reliability of the amplifiers, the use of vacuum tubes should be avoided. Demodulators using selenium rectifiers in a balanced bridge arrangement are available commercially, but the unbalance with zero input signal is generally intolerable for low-level servo applications. The relatively high threshold voltage of a selenium rectifier makes the demodulation of signals below several hundred millivolts difficult and good linearity is difficult to obtain at low voltage levels.

A demodulator circuit that does not suffer from the disadvantages of the selenium rectifier units but that avoids the use of vacuum tubes is shown in Fig. 1. It is a transistor demodulator that has been combined with a stable, high-gain 2-stage magnetic amplifier to produce a unit that is very effective in a synchro-controlled position system.

Operation

The demodulator circuit is one of a newly developed class of transistor circuits in which the transistors are used as switches.[1] An alternating reference voltage is applied between the base and collector of the PNP transistors. When the base is positive with respect to both the emitter and collector, the transistors will act as open switches with very low leakage. When the base is negative with respect to either, the transistors will act as closed switches with very low voltage drop.

The modes of operation are illustrated in Fig. 2. The transistor pair, when acting as a closed switch, will pass current in either direction if the reference source supplies sufficient base current. Since the transistors are being used as switches rather than as amplifiers, their characteristics are not critical and the units do not have to be carefully matched. Furthermore, the transistors can have poor amplifying characteristics and still

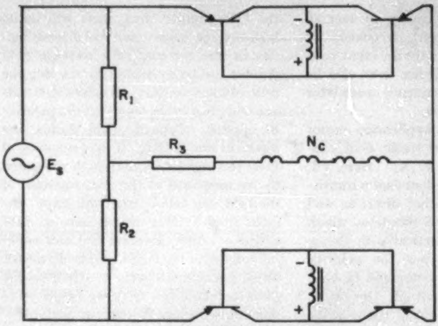

Fig. 1. Circuit diagram of transistor demodulator

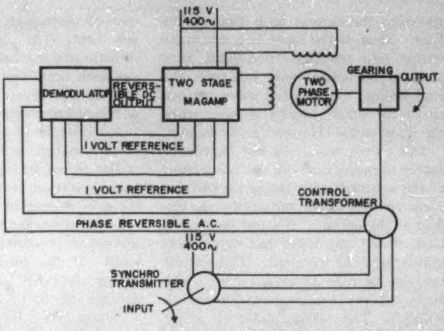

Fig. 3. Position servomechanism using transistor demodulator combined with 2-stage magnetic amplifier

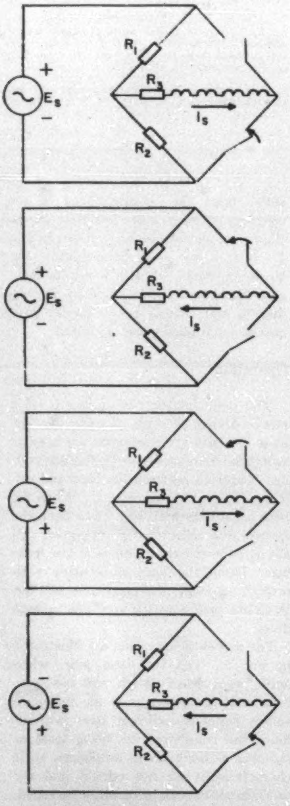

Fig. 2. Modes of operation of transistor demodulator

be successfully used. The property which is most important is the Zener voltage characteristics of the transistors. The maximum signal voltage E_s appears across the emitter-collector junction of one transistor during the time in which one pair of transistors is acting as an open switch; thus, the junction must be able to withstand the peak voltage which the signal source can supply. For many synchros this maximum voltage is 30 volts rms, and the transistors must then have a Zener voltage of 42 volts.

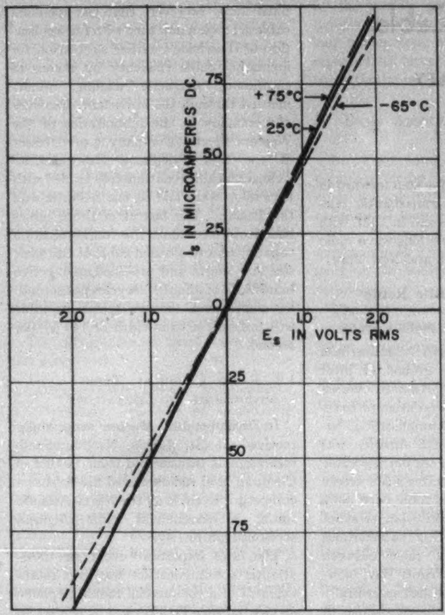
In the circuit of Fig. 1, two resistors, R_1 and R_2, are shown; these are used to provide a split signal source. However, in some applications, these can be replaced by a split secondary of an input transformer. The two resistors R_1 and R_2 do not have to be carefully matched because, as can be seen from Fig. 2, for either phase of the alternating voltage to be demodulated, the circuit operation must be symmetrical and the balance of the unit will not be affected by an unbalance in R_1 or R_2. The nominal value for this application is 10,000 ohms because the recommended minimum load for a synchro control transformer is 10,000 ohms. It can be seen from Fig. 2 that, for very low values of load resistance, the minimum resistance seen by the signal source is $R_1 = R_2$. For other applications, the resistors R_1 and R_2 may be chosen to be any value with the minimum value being set by either the loading of the signal source or the maximum permissible current of the transistors. Of course, the resistance of the load will have to be considered also because of the current division between the load and bridge resistances. R_3 in many applications is the resistance of the control windings, with no external resistance being necessary.

The reference voltage needed for switching the transistors is approximately 1 volt and is supplied from two separate secondary windings of transformer T_1. The reference voltage should be as nearly as possible in phase with the voltage of the signal source because the transistors block only when the proper polarities exist between the various terminals. In the experimental unit discussed subsequently, the reference voltages were obtained by adding two additional secondary windings to the supply transformer of the first stage of the 2-stage magnetic amplifier.

Experimental Characteristics

To illustrate a practical application, the demodulator has been combined with a 2-stage magnetic amplifier that has a high-volt-per-ampere-turn gain when direct current is supplied to the control windings. A typical system is shown in Fig. 3. The control transformer will supply a phase-reversible 400-cycle voltage that will be a measure of the relative position of the shafts of the control transformer and synchro transmitter. The voltage gradient of the control transformer is 400 millivolts per degree with a maximum output voltage of 27 volts.

The d-c output current versus applied voltage characteristic of the demodulator was measured at room temperature, −65 degrees centigrade and at +75 degrees centigrade. The unit was kept at the extremes of temperature for 4 hours before the measurements were made. The curves are shown in Fig. 4. With R_3 equal to 2,000 ohms, the null point shift under temperature extremes is less than 1



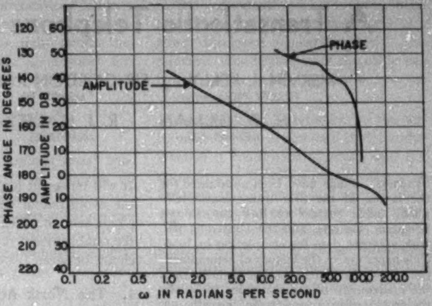


Fig. 4 (left). D-c output current versus a-c signal voltage characteristics of transistor demodulator

Fig. 5 (above). Frequency - response characteristics of position servomechanism

microampere. The data plotted in Fig. 4 were taken with voltage applied from the control transformer. In this particular system, control transformer voltage is not exactly in phase with the reference voltage applied between the transistor terminals; thus, the rectification efficiency of the demodulator is 78 per cent.

It will be noted that the characteristics remain linear even at small voltages. This linearity exists for voltages at least as small as 20 millivolts, which is the noise level of the synchro units. The influence of the magnetic amplifier on the demodulator, and vice versa, was tested by measuring the output current of the demodulator, both with the amplifier control winding short-circuited and with it connected. The difference was no greater than that caused by the resistance of the control winding alone. The effective resistance of the demodulator which determines the time constant of the first-stage amplifier is

$$\frac{R_1R_2}{R_1+R_2}+R_3$$

if the internal resistance of the signal source is neglected. For most applications, the effective resistance can be maintained at approximately 10,000 ohms, and the first-stage amplifier can be made to have a response time no greater than 3 or 4 cycles of the supply frequency. The first stage, which is usually a d-c to d-c amplifier, can then be treated as an operational magnetic amplifier.[2] Series lead or lag networks can be used with the d-c to d-c amplifier, or feedback through frequency sensitive networks around the amplifier can be used to provide system compensation.[3] Fig. 5 is a plot of the frequency-response characteristics of the system shown in Fig. 3. The amplifier response has been extended by negative integral feedback around the first stage and by a series compensating network between amplifier stages. The negative integral feedback network supplies a steady-state feedback to stabilize the amplifier against temperature, voltage, and frequency variations. By using negative feedback in this manner, it has been possible to reduce the drift level of a magnetic amplifier position servomechanism with a transistor demodulator to a position error of 0.1 degree over an ambient temperature range of −65 to +71 degrees centigrade, and with 10-per-cent variations in supply voltage and frequency.

Conclusions

The transistor demodulator described in this paper is a stable detector and demodulator capable of operating at signal voltage levels at least as low as 20 millivolts and as high as 30 volts rms with low drift over the temperature range from −65 to +75 degrees centigrade. It is extremely well suited for operation in a synchro-controlled system because it can be readily combined with a stable, full-wave magnetic amplifier.

The magnetic amplifier-transistor demodulator combination makes a stable, high-gain amplifier that will amplify a-c signals and still enable the full amplification capabilities of the magnetic amplifier to be utilized. For synchro-controlled systems, the sensitivity and drift stability are great enough so that errors caused by inaccuracy in the magnetic amplifier-transistor combinations are not limiting factors in the over-all servo performance.

Synopsis: Plans have been announced for the laying of the first transatlantic telephone cable system to link the United Kingdom, Canada, and the United States, with a target date for completion in 1956. This paper traces the history of communication across the North Atlantic and discusses the inadequacy of radio circuits to satisfy the requirements of traffic growth. A general description is then given of the cable system which will provide 36 telephone circuits across the Atlantic and 60 between Newfoundland and Nova Scotia. The project has been made possible only by the development of submerged repeaters containing long-life vacuum tubes and other components, and these are described, as well as the American experimental work that led to the development of a flexible repeater housing which could be laid at depths of 2 miles without risk of damage to itself or to the cable. Fifty-two of these repeaters will be used in each of two 1-way cables, nearly 2,000 nautical miles long, connecting Newfoundland with Scotland. Newfoundland will be connected to Nova Scotia by a single cable containing 16 2-way repeaters of British design evolved from that which has been extensively used for schemes in home waters.

IN DECEMBER 1953 plans were announced by the American Telephone and Telegraph Company, the British Post Office, and the Canadian Overseas Telecommunication Corporation for the laying of the first transatlantic telephone cable system. The system will provide 36 high-grade telephone circuits between the United Kingdom, Canada, and the United States, and commercial operation is contemplated at the end of 1956.

In scope the project far exceeds anything that has been attempted hitherto; the two cables on the main crossing will each be nearly 2,000 nautical miles* long and each will contain 52 submerged repeaters, laid at depths of up to 2,000 fathoms, whereas at the time of writing the longest submarine telephone cable is less than 200 nautical miles long and no cable contains more than four repeaters. The American Telephone and Telegraph Company and the British Post Office have joint engineering responsibility for the project, which is the outcome of studies and experiments started many years ago. It will represent a major step forward in the evolution of the transatlantic telephone service which began in 1927 with the establishment of one long-wave radio circuit between London and New York.

1. The North Atlantic Route

1.1 The Early Telegraph Cables

Historically, the North Atlantic route has been the proving ground of most major advances in long-distance oversea communication. The first attempt to establish telegraphic communication between Europe and North America was made by cable in 1857–58, but the cable failed in October 1858 after a few weeks of service. In 1865 the route once more became the scene of activity, but it was not until the following year that the hazardous operation of laying a cable between Valentia, Ireland, and Trinity Bay, Newfoundland, was accomplished successfully and the North Atlantic route opened to electrical communication.

The successful completion of the first transatlantic telegraph cable was due to the foresight, courage, and determination of Cyrus W. Field, an American, coupled with an outstanding British technical accomplishment of its day. The communication capacity of the cable was, however, very limited. Dr. O. E. Buckley noted in the 1942 Kelvin Lecture[1] that, even with the improvements in terminal apparatus and operating techniques introduced by Sir William Thomson (later Lord Kelvin) and his associates, the first transatlantic cable operated at a speed of only 3 words per minute. This required a bandwidth of perhaps 1.5 cycles per second.

To meet the increasing demand for rapid communication across the North Atlantic which arose after the first cable went into operation, more cables were laid and there are now some 20 in operation on this route.[2] The best available scientific talent, particularly in the United Kingdom, was devoted to increasing the efficiency of the early cables, and late nineteenth century research on submarine telegraph cables and their terminal apparatus may well be one of the first examples of the large-scale effectiveness of applied research. It was not, until 1924, however, that the deep-sea cable art took a new turn with the application of Heaviside's earlier suggestion for increasing cable efficiency by means of continuous magnetic loading, implemented through the important discovery of permalloy in the laboratories of the Western Electric Company, a predecessor of the Bell Telephone Laboratories.[3] Telegraph cables continuously loaded with permalloy were laid in the Atlantic and the Pacific. The fastest of these cables had about four times the communication capacity of a nonloaded cable of the same size and length and provided an effective bandwidth of about 100 cycles per second. By comparison, the new telephone cable will transmit a bandwidth of 144 kc per second.

1.2 Radio Circuits: Their Advantages and Limitations

In December 1901 Marconi successfully received at St. John's, Newfoundland, radio signals transmitted from Poldhu in Cornwall, and radio entered the field as a competitor to cable on the North Atlantic route. A commercial radio-telegraph service began in 1908.

The next important event in transatlantic communication was the establishment of a commercial radio-telephone service between London and New York in January 1927, when the long-wave radio transmitting stations at Rugby and Rocky Point were brought into operation. The circuit used the single-side-band suppressed-carrier technique which has since found universal application for both radio and cable telephone circuits. Another important event was the opening of the short-wave (high-frequency) radio spectrum to long-distance communication. Short waves were introduced on the transtlantic route in 1928, and there are, at the time of writing, 14 short-wave radio

* One telegraph nautical mile or naut = 6,087 feet = 1.153 statute miles.

Paper 55-230, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing December 3, 1954.

Mervin J. Kelly and G. W. Gilman are with the Bell Telephone Laboratories, Inc., New York, N. Y., and Sir Gordon Radley and R. J. Halsey are with the Post Office of the United Kingdom, London, England.

The concept of a transatlantic telephone cable owes its origin to the inspiration of Dr. O. E. Buckley's early work, for he laid the firm technical foundation for such a project. The subsequent developments recorded in this paper have been the work of many engineers on both sides of the Atlantic; on the American side in the Bell Telephone Laboratories, the Western Electric Company, and the Simplex Wire and Cable Company; on the British side in the Post Office Research Laboratories, Standard Telephones and Cables Limited, and Submarine Cables, Limited. Without this work the particular project described would have been impossible.

telephone circuits between the United Kingdom and the United States and two between the United Kingdom and Canada. Both events were to have an indirect but important effect upon the subsequent development of submarine cables. The availability in the early 1930's of comparatively wide-frequency bands for short-wave radio communication, the economic depression of that period, and other factors combined to defer whatever plans there may have been to lay additional telegraph cables across the North Atlantic. On the other hand, recognition of the technical limitations of radio for transatlantic telephony soon led to studies of the feasibility of a North Atlantic submarine telephone cable.

The advantages of short-wave operation have been:

1. Comparatively low-cost installations.
2. Flexibility, i.e., ease of establishing taking down, and rerouting circuits.
3. Direct access country to country.

With respect to the last point, it is of interest to note that arrangements have come into effect to route certain transatlantic traffic through radio-relay stations favorably located to avoid zones where ionospheric conditions are most frequently disturbed. On the other hand, the following disadvantages of short waves are familiar:

1. Although, when ionospheric conditions are stable, short-wave operation furnishes satisfactory transmission, no way has been found to provide day-to-day continuity and reliability comparable to that of good wire lines.

2. The deficiencies of short-wave operation are particularly marked on the North Atlantic route, which is exposed to severe ionospheric disturbances. (The past 25 years have been characterized by three periods of very severe disturbance. The first period covered about 3 years around 1930; the second, more moderate in effect and of shorter duration, centered at 1944; and the last, which is particularly serious started in 1950 and is still in progress.)

3. The short-wave radio spectrum has become overpopulated with time. Interference between services is an increasingly serious problem and, even when full allowance is made for the development of multichannel working on a single transmitter the number of transatlantic circuits could not be increased very greatly.

The original long-wave radio-telephone circuit, which is still in use, renders an important service in providing limited communication facilities when the short-wave circuits are not serviceable. However, the entire long-wave spectrum has a frequency bandwidth of less than 100 kc per second and, since this must be shared by the world's communication services (telephone and telegraph) which need long waves, long-wave radio cannot be regarded as more than an adjunct for transatlantic telephony.

2. Early American Work

In 1919 a small American group was organized under Dr. O. E. Buckley to study ways of increasing the transmission capacity of long, deep-water submarine cables; this was in accordance with the emphasis in all American submarine cable work on the problems of deep-water cable technology.

The first work of this group was, however, with short lengths of telephone cables at medium depths. In 1921 three iron-wire (Krarup)-loaded cables were laid between Havana and Key West, a distance of just over 100 nautical miles. These were the first cables made with an outer copper return conductor giving a coaxial structure. In deep-sea telegraph cable practice the custom had been to depend upon the sea itself and the armor wires of the cables as a return medium, but this is not satisfactory at telephone frequencies. Each of the three Key West-Havana cables provided sufficient frequency bandwidth to accommodate one telephone and three carrier telegraph circuits in addition to a d-c telegraph circuit. Two years later two cables were put into operation over the 23-nautical-mile route between the California shore and Catalina Island, and these were ultimately operated at frequencies up to 35 kc per second. The Key West-Havana and the Catalina cables were operated as 2-way cables, i.e., each cable was used for both directions of transmission simultaneously. Separation of the two directions of transmission was by means of balancing circuits at the terminals. There soon followed the developments in long, deep-water, high-speed submarine telegraph cables which were mentioned earlier.

By the late 1920's developments in submarine cable technology and in magnetic and insulating materials reached a point where a single-circuit telephone cable across the North Atlantic between Ireland and Newfoundland (a distance of 1,800 nautical miles) seemed feasible. A specific proposal to this effect was formulated by the Bell Telephone System in 1928 and discussed with the British Post Office. The proposal called for laying a single, continuously loaded, nonrepeatered coaxial cable, operating at a top frequency of about 3,800 cycles per second and providing a single telephone circuit. The central conductor was to have been loaded with wrappings of tape made of a newly developed magnetic material, perminvar. The insulation of the cable was to have been paragutta, also a new development.

As a check on the estimates of the performance of this design, and to determine whether it could be successfully laid and recovered, a 20-mile section was manufactured in Germany and laid in deep water in the Bay of Biscay in 1930. This was subsequently recovered and relaid in shallow water. A length of nonloaded cable with paragutta insulation was laid the same year between Key West and Havana. The projected cable was never laid across the Atlantic, principally because of economic conditions. However studies and experiments in the laboratory and at sea, looking toward a new and better cable, continued during the depression following 1930.

During the laying and recovering operations in the Bay of Biscay in 1930, "kinking" of the cable and buckling of the conductors occurred on several occasions. This extreme local deformation was caused by unwrapping of the armor wires at points along the cable. The damage is caused in the following way. As the cable passes aft of the ship, variations in tension cause twisting and untwisting of the cable structure; this twisting is harmless if it is distributed along the length of the cable, but if it is localized for any reason buckling can occur. Stopping and starting of the cable ship, or the existence of any large irregularity along the cable itself, are potential causes of damage; e.g., severe local distortion was produced artificially during the Bay of Biscay tests when a large board, nicknamed the "barn door," was lashed to the cable.

The structure of the proposed coaxial transatlantic telephone cable was inherently much more complex than that of the conventional nonloaded deep-water telegraph cable. The cable was therefore more subject to damage while being handled at sea and, because of the serious consequences of such damage, great attention was paid to the problem of maintaining the structure of the cable unaltered during laying operations. Laboratory studies led to a design in which the lays of the tape loading, the tapes of the copper inner and outer conductors, and of the armor wires were in the same direction. This was a departure from established thinking at the time, but has been carried through in the subsequent cable designs of the Bell Telphone Laboratories.

3. Multichannel Transatlantic Cable Project: Background of American Experience

By 1928, when the proposal for a transatlantic telephone cable was first formulated, electronic techniques were well established in land cable practice, although they had not reached the point when serious proposals could be made to lay a transatlantic submarine cable with submerged repeaters lying on the ocean bottom. For this to become feasible further improvements in technology were required, notably the use of amplifiers stabilized by negative feedback and pentode tubes with equipotential and uncombined cathodes. These developments, which were to make long-distance multicircuit carrier telephony a reality within the next 10 years, as well as still greater reliability, were needed to make the transatlantic plan practicable. Until these improvements became available, the only kind of repeatered transatlantic system that could be imagined was one in which the repeaters would be mounted on moored platforms at sea or would be in submerged buoys, fed with power from local batteries and visited at intervals for maintenance and repair. Systems of this kind were considered and discarded as impracticable.

By 1932 great advances were being made, and the first experiments on long-distance broad-band systems for use on land were well under way. While the solution of many of the submarine cable problems was not yet clear, the rapidly developing electronic art created the atmosphere of confidence that made it possible to contemplate seriously the design of a long-distance deep-water cable associated with submerged repeaters in which were long-life tubes which would be capable of transmitting a number of carrier telephone channels instead of only one channel.

The broad concept which grew up concerning the transatlantic cable system was the use of two nonloaded coaxial cables, one for each direction of transmission, into which repeaters would be spliced at regular intervals. Detailed discussion of the merits of two cables versus one is outside the scope of this paper. Suffice to say that an economic field for the use of twin cables (1-way operation in each) may be on long deep-water routes with traffic growing rapidly beyond the capacity of a single-cable system. In this case, however, the choice was influenced by the need to use repeater housings which would cause the minimum irregularity in the cable structure. As will be pointed out in section 4, 2-way repeaters for use in a single-cable system require more space in the repeater housing than do repeaters for 1-way operation.

The repeaters required for the transatlantic cable system had to be designed to withstand the shocks of laying and recovery and also the pressure of water encountered at the greatest depth on the North Atlantic route. The tubes used had to operate at sufficiently low cathode power and anode potential to make it feasible to supply power to the repeaters over the cable from the shore ends at a safe working potential. This potential was eventually established at roughly 2,000 volts d-c. Finally, the repeaters had to be long-lived enough to operate with small likelihood of failure over a period of time (generally taken as 20 years) which would be long enough to make the enterprise as a whole technically sound and economically attractive.

3.1 Repeater Housing

Early experience of the potential hazards of damage to, or modification of, the structure of the cable during handling led to the objective of a flexible housing, structurally as nearly as possible like the cable, and which could, without damage to itself or the cable, be passed over the drum and sheaves of the cable ship and paid out without slowing up or stopping the vessel. The so-called "snake-type" housing for the tubes and other repeater elements was developed; it will be described in section 7.2.

3.2 Long-Life Tubes

The tube finally adopted was a conservatively designed suppressor-grid pentode whose details were finalized in 1941 and which has not since been changed in any essential way. It is a tube with large cathode area, low cathode temperature (630 degrees centigrade), low plate potential (60 volts), large internal spacing between elements, and of generally rugged and shockproof construction. Some of these tubes have been under continuous test for a period of over 13 years and 18 have been in operation for 4 years in repeaters on the most recent Key West-Havana cables.[4] All indications are favorable for something better than 20-year life expectancy for North Atlantic service.

3.3 Components

In addition to the tubes, about 60 other circuit elements have to be accommodated inside the submerged repeater housing. These include resistors, capacitors, inductors, transformers, and crystals. Like the tubes, these elements must be designed and fabricated so as to avoid all possible risk of failure in service. They must also meet requirements of ruggedness and reasonably small size. Cost, fortunately, is a less important factor than it is in most other applications.

The failure of any one of the other components could be as serious as that of a tube, and a 5-step philosophy was evolved in the Bell Telephone Laboratories for their selection and manufacture, aimed at achieving as near perfection as humanly possible. The steps are as follows:

1. Draw on the background of experience with similar parts in use in the telephone plant.
2. Supplement experience with extraordinary care in selecting material and with special testing of components during production and after completion.
3. Use an open and simple structure to avoid hidden errors.
4. Select and train personnel for perfection of skill and pride in product.
5. Develop the worker's faculty of self-criticism so that only those parts are submitted which truly represent his best efforts.

In this way there was incorporated into the development of each component all the knowledge and integrity that American telephone practice and experience provided. Wire-wound resistors, for example, have been made for 50 years, and there are something like 50,000,000 of them in service. This type of resistor was therefore chosen for the submerged repeater in preference to the deposited-carbon resistor which is of more recent origin. Similarly, experience in the control of materials and quality production and experience in the telephone operating field were drawn upon in the selection of designs of permalloy-core inductors and paper and mica capacitors. This experience was supplemented wherever possible by accelerated life tests.

Care in the control of materials used for the repeater elements has been particularly important. A case in point is the selection of paper for the capacitors. Large quantities of this paper are purchased annually for the manufacture of capacitors for use in the general telephone plant; the paper is supplied in lots which are submitted to accelerated life tests. The lots which performed best in an interval of 6 months were made available to the Laboratories, where every roll was reinspected and only those showing the highest life were chosen for the capacitors.

3.4 Cable

The design of cable finally decided upon consists of a solid dielectric coaxial structure covered by the usual jute and armor for protection and strength. The composite central copper conductor consists of a central solid wire surrounded by a single layer of spiralling and abutting tapes carefully formed to fit closely about the wire with a minimum of voids. Such a composite structure has better flexibility and protection against breakage than a solid conductor, and has better a-c and d-c resistance than a stranded-wire conductor of the same outside diameter. The return conductor is also a flexible composite copper structure consisting of a single layer of abutting spiralling tapes, carefully formed into a tubular configuration. It is covered with an overlapping, spiralling copper tape for teredo protection. The various spiralling layers of tape and armor are all applied in the same direction of lay for reasons stated in section 2.

The original coaxial cable designs had used paragutta as the dielectric, but shortly before World War II representatives of the Post Office brought polyethylene (polythene), a British development of Imperial Chemical Industries, to the attention of the Bell Telephone Laboratories. On test it proved to have characteristics which made it superior to paragutta. It had a lower dielectric constant and higher dielectric strength, was more uniform in its characteristics, was less pervious to sea water, and had mechanical properties which made it more desirable. Polyethylene was soon adopted as a feature of the proposed transatlantic cable.

3.5 Key West-Havana Cables

During World War II the American group concerned with the cable was reduced to the barest minimum necessary to keep the development alive, but a machine to simulate cable-laying operations was constructed and used to test ideas concerning repeater housings.

Upon the cessation of hostilities the decision was taken to install on the Key West-Havana route a pair of cables of the design that had been evolved for transatlantic service. A special air-conditioned repeater assembly shop was set up at the Laboratories and a contract was entered into with a manufacturer for experimental cables. Arrangements were also made with the Western Union Telegraph Company for modification to the cable ship *Lord Kelvin*. By 1948 work had progressed to a point which enabled 20 nautical miles of cable and repeaters, together with special built-in testing facilities (accelerometers) for observing and measuring shocks to the cable during handling, to be laid in depths up to 2 nautical miles in the Bahamas. During this period of growing activity, methods of cable manufacture, including testing and quality control, were worked out in co-operation with the manufacturer.

This work culminated in May 1950 with the laying of the Key West-Havana cables (115 and 125 nautical miles).[4] The cable system includes six repeaters, five of which are on the ocean bottom at depths ranging from 20 fathoms to 950 fathoms. The sixth repeater is located in a cable vault on the shore near the Havana telephone office. These repeaters have been in operation, at the time of writing, for 4 years without failure and without indication of deterioration.

4. British Shallow-Water Experience

Many submarine telephone cables connect the United Kingdom to the continent of Europe. These are of a variety of types and lie in water which is nowhere deeper than 300 fathoms. The first coaxial cable of modern type, and generally similar to the cable described in section 3.4, was laid in 1937 and used paragutta dielectric. All postwar coaxial cables, however, have been constructed with polyethylene.

British development of submerged repeaters for existing cables has recently been described.[5–7] Experimental work by the Post Office did not start until 1938, but in 1943 a coaxial cable between Angelsey and the Isle of Man was equipped with a shallow-water repeater.[8] In 1946 a repeater was inserted into a cable between Lowestoft and Borkum to provide direct telephone communication to the British Armed Forces in Germany. These were the first uses of submerged repeaters for telephone traffic anywhere in the world. In these two early applications, GO and RETURN speech channels were provided over a single cable and separated on a frequency basis, the repeater being arranged to amplify only the channels transmitted in the high-frequency band.

The Post Office next turned its attention to the development of submerged repeaters suitable for operation in tandem and designed to transmit a supergroup of 60 circuits over existing coaxial cables.[9] At this stage a decision became necessary as to whether British development should continue to be in accordance with a pattern of transmitting GO and RETURN channels over a single cable, which was the established practice with nonrepeatered systems, or whether separate cables should be used for the two directions. Use of separate cables for the two directions of transmission meant greater simplicity of equipment, but Post Office experience with the inherent difficulties of submarine cable maintenance in the North Sea had led to a firm preference for making every cable self-contained in respect to circuits on which the traffic did not necessitate more than two or three cables on a route.

It was decided, therefore, that the repeaters should be designed for 2-way transmission. The primary supergroup of 60 speech channels is, by international agreement, assembled in the frequency band 312 to 552 kc per second, and the system was arranged to transmit this frequency band in one direction and the frequency band 24 to 264 kc per second in the other. High- and low-pass filters were necessary to separate GO and RETURN channels at each repeater, but these were arranged to feed into a common amplifier.

The directional filters, necessary for 2-way transmission, waste a part of the frequency spectrum, while the added components somewhat increase the probability of premature failure and require additional space in the housings. The loss of frequency spectrum and slightly increased risk of failure were not considered important in comparison with the operational advantages of single-cable systems, and the additional space required was not a serious problem because experience had shown that the large single-ended housings which were in use at the time could be laid and recovered without difficulty in shallow water.

The system evolved, which may include up to ten intermediate repeaters, appears adequate for all routes between the United Kingdom and Europe. It was first installed in 1950 and about 20 repeaters are in operation at the time of writing. Very similar 36-circuit systems have been in operation for 4 years between the Netherlands and Denmark.[7]

These earlier projects, while profitable and affording valuable experience, did not lead directly to a design suitable for a transatlantic project or for installation elsewhere at ocean depths. In 1948, however, the Post Office began to study the possibility of using submerged repeaters to increase the traffic capacity of the telegraph cables operated by Cable and Wireless Limited, and development of a housing suitable for installation in deep water was commenced in collaboration with a manufacturer. The design was modified after laying tests in 2,700 fathoms in the Bay of Biscay in 1951 which were carried through under ad-

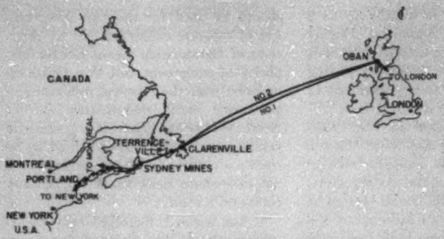

Fig. 1. Route across the Atlantic

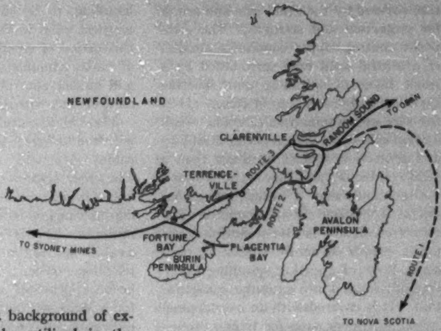

Fig. 2. Routes in Newfoundland

verse weather conditions and were not entirely successful. This housing, described in section 8.3, is rigid, like the shallow-water unit, but is double-ended and much smaller. It is in line with the cable, designed to transmit the full laying tension experienced in deep water, and is able to rotate freely during the laying operation. Limited tests were carried out in the Mediterranean Sea at depths of 250 fathoms in the autumn of 1953, when lengths of cable including the new repeaters were repeatedly laid and recovered. Twist, tilt, and recording devices included in one repeater housing established that the repeater could be handled and laid without significant bumping. It has yet to be established that the design is suitable for use in very deep water and that, in particular, the laying operation does not endanger the cable by the insertion of slack which subsequently tightens into kinks.

The Post Office did not commence serious study of the transatlantic problem until 1950 when it set up a committee to report on the future possibilities of repeatered telephone cables on this route. In 1952 it was decided to engineer a new telephone cable of about 300 nautical miles between Scotland and Scandinavia as a prototype for a system suitable for water of greater depth than that actually on the route, although this is no more than about 200 fathoms, and the requirements of 36 circuits on a single cable could have been met using the proved shallow-water repeater design. The cable was laid in the autumn of 1954. An innovation in submerged repeater circuit design is the use in each repeater of parallel connected amplifier units with two separate forward paths and a common feedback path. The tubes will be of a long-life type developed in the Post Office Research Laboratories for submerged repeater applications.

The decision to use deep-water-type repeaters for this system was an important step in building up a background of experience which will be utilized in the Newfoundland-Nova Scotia section of the transatlantic system.

5. Decision on Transatlantic Telephone Cable Project

Early in 1952 negotiations were once again opened between the American Telephone and Telegraph Company and the British Post Office. Two of the authors, Kelly and Radley, reported jointly on the status of submerged repeater development in the United States and in the United Kingdom after independent studies by engineers of the Company and of the Post Office.

At that time the American development had been completed in its basic features for several years. The tubes and other components, initially constructed or selected for reliability in service, had been under life observation since about 1940. Cable and repeater designs for a transatlantic project had been subject to stringent laboratory tests and had finally been given the practical trials, already referred to, on the Key West-Havana route. The authors concerned recommended that these designs should be used for the long link between Newfoundland and Scotland, because proved reliability is an essential requirement in a pioneering and costly venture of the difficulty of a transatlantic telephone cable. This is evident.

There had not been an opportunity to subject to comparable tests the elements in the British development, particularly those which it was proposed to introduce as parts of a deep-water, as distinct from a shallow-water, system. Nevertheless it was apparent that if means for laying and recovering the large repeater housings in deep water without damage to the cable were later developed the design would provide great flexibility in repeatered cable systems of the future. The authors therefore recommended that the British design should be used for the link between Newfoundland and Nova Scotia, where the water is of moderate depth and offers the opportunity for observation of a design based on proved shallow-water techniques. The design because of its later initiation, permitted of a lower cost per telephone circuit on this short link.

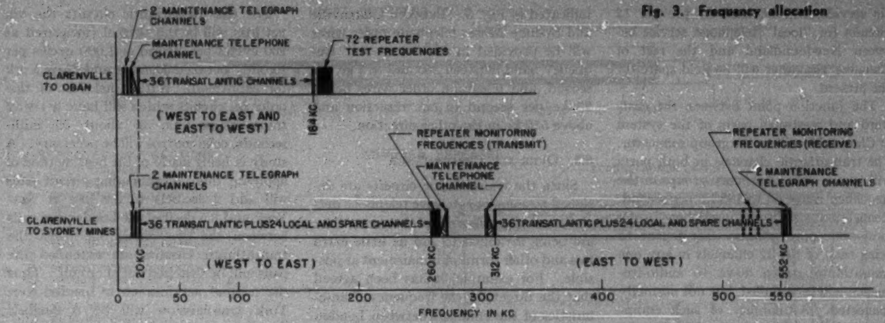
The Canadian Overseas Telecommunication Corporation was asked to join in the enterprise, because of its interest in overseas communication and because of the desire that the project should also improve United Kingdom-Canada communication. Administrative and technical discussions took place on both sides of the Atlantic, and agreements were arrived at and formalized in a contract signed on November 27, 1953. Ownership of the system will be vested in the American Telephone and Telegraph Company, the British Post Office, the Canadian Overseas Telecommunication Corporation, and the Eastern Telephone and Telegraph Company. The latter is a subsidiary of the American Telephone and Telegraph Company and will be concerned with the facilities within Canadian territorial limits.

6. General Description of the Complete System

6.1 Route

A map of the system is shown in Fig. 1, and the route in Newfoundland is shown in greater detail in Fig. 2. The route between Clarenville in Newfoundland and Oban in Scotland has been chosen so as to be well clear of existing telegraph cables, which lie to the south, and also to avoid known "holes" in the sea bed. Selection of a landing site in Newfound-

Fig. 3. Frequency allocation



land was determined by the following considerations:

1. The cables remain in deep water until they enter the northwest arm of Random Sound, where damage is not to be anticipated from grounding icebergs.

2. There is no crossing over other cables.

3. Clarenville provides reasonable amenities for the staff who will have to maintain equipment associated with the cables to Scotland and Nova Scotia.

Both the cables between Clarenville and Oban will be approximately 1,950 nautical miles long, and each will be equipped with 52 repeaters. The greatest depth at which a repeater will lie will be approximately 2,300 fathoms (2.6 statute miles), but most will be at depths between 1,200 and 2,000 fathoms.

Three alternative routes connecting Clarenville with Nova Scotia were considered; none was very attractive from an engineering standpoint. They were:

1. To leave Clarenville generally in an easterly direction and to lay the cable in a wide sweep round the Avalon Peninsula and in deep water to the south of the Newfoundland Banks.

2. To leave Clarenville generally in a southerly direction, cross the Avalon Isthmus (about 5 miles wide) into Placentia Bay, cross the Burin Peninsula (about 10 miles wide) into Fortune Bay, and thence in water of moderate depth to Sydney Mines.

3. To lay the cable overland to Terrenceville at the head of Fortune Bay, thence picking up the same inshore route as in item 2.

The first of these would have involved a cable 600 nautical miles long crossing a number of existing telegraph cables; the second, while avoiding the main fishing grounds and other cables, would have necessitated landings at four intermediate points. Therefore, after an on-site investigation, the last alternative was chosen. This part of the system thus falls into two parts: to the east about 62 statute miles overland, and to the west about 274 nautical miles in coastal waters at depths up to about 250 fathoms. The single cable will be equipped with 16 repeaters, two of which will be on land.

6.2 CIRCUIT CAPACITY

Fig. 3 shows the location of the various frequency bands used for transmission and the location of various pilot tones. The cables between Clarenville and Oban will have transmission frequency bands extending from 20 to 164 kc per second and will provide capacity for 36 carrier telephone circuits, with channels at 4 kc per second spacing. The capacity of the cable between Clarenville and Sydney Mines will be somewhat greater, because it is planned to transmit the frequency band 20 to 260 kc per second from Sydney Mines to Clarenville, and the frequency band 312 to 552 kc per second in the reverse direction. The cable will therefore provide 60 carrier telephone circuits with channels spaced 4 kc per second apart. One of the two 12-channel groups in each direction, not employed for transatlan-

NOTE: AT OBAN AND SYDNEY MINES THE SCHEMATICS ARE COMPLEMENTARY TO THOSE OF THE FACING EQUIPMENT AT CLARENVILLE tic service, will be used to provide 12 circuits for "local" telephone service between Newfoundland and the rest of Canada; the other will be held spare for the present.

The junction point between the eastward and westward parts of the system at Clarenville will be the group connector. The transatlantic channels in both parts will appear here as primary groups in the frequency range 60 to 108 kc per second. Connection will also be made here to the local and spare groups. Equipment to bring each of the 12 channels in any one transatlantic group down to audio-frequency will be installed, but not normally connected. Availability of such equipment is desirable in order to enable impairments affecting only one or two channels to be localized to one part of the system. Fig. 4 is a schematic of the arrangements at Clarenville. The arrangements will be similar at Oban and Sydney Mines.

The traffic operating terminals will be in London, New York, and Montreal. Twenty-nine telephone circuits will be put into service between London and New York and six between London and Montreal. Telegraph circuits between London and Montreal will be provided in the upper half of the 36th telephone circuit.

Telephone and telegraph circuits for maintenance purposes will be provided between Oban and Clarenville in the frequency band below 20 kc per second, as indicated in Fig. 3. Between Clarenville and Sydney Mines telephone order wires will be provided in the "crossover" frequency band between 260 and 312 kc per second, and telegraph order wires below 20 kc per second in one direction and above 552 kc in the other direction.

6.3 Over-all Performance

Since the transatlantic circuits are designed to connect extensive telephone networks on opposite sides of the ocean, they are being arranged to add as little extra loss and other forms of impairment as possible. For example, it has been agreed that the target for the frequency characteristics of the channels between London and New York, or London and Montreal, should be as good as that recommended by the Comité Consultatif International Téléphonique for a 2,500-kilometer international carrier circuit. Other objectives for the circuits compare favorably with those specified for long-distance circuits wholly on land.*

For the transatlantic circuits the via net loss will be 0.5 decibel (measured at 800 cycles per second or 1,000 cycles per second) between London and New York (or Montreal). With a net loss of this order on circuits which will have a 1-way transmission time of about 35 milliseconds, echo control will be necessary. A study is being made of the best method of applying this. Terminating circuit pads will add 2 decibels to the loss at New York and 3.5 decibels at London for calls between the two cities, but when the transatlantic circuits are extended the pads will be switched out of circuit. Thus the normal net loss on a London-New York transmission will be 6 decibels (3.5 + 0.5 + 2), or slightly more than the objective for Regional Center to Regional Center connections in the United States or Canada. It is an agreed objective to restrict variations from the specified net loss to a standard deviation of 1.5 decibels. This will put a severe requirement on the individual links which may be difficult to meet. In all respects the requirements for the Sydney Mines-Clarenville-Oban cable sections have to be somewhat more stringent than for the over-all circuits.

A pilot tone at a frequency slightly displaced from 84 kc per second will be injected into each group of 12 channels at a point where the channels appear in the 60- to 108-kc-per-second range. Measurements of the received level of the tone will give an indication of the over-all net loss; later the received tone may be used to control automatically the gain of terminal amplifiers on each group. In addition, 92-kc-per-second pilot tones, similarly injected, will be transmitted over each cable section to give an indication of the net loss of the section. These tones will be blocked from passing from one section to another.

Signaling over the cable circuits will be designed to allow co-ordination between the different national long-distance signaling systems at the ends.

7. Clarenville-Oban Section

As already indicated, two cables will be used between Newfoundland and Scotland, one for each direction of transmission. These and the associated repeaters will be of the type now in operation between Key West and Havana, and have been described in some detail in the technical literature.[4]

7.1 CABLE

The evolution of the cable design has been described in sections 2 and 3.4. The cable to be used on the transatlantic route will have a somewhat greater thickness of dielectric than that included in the make-up of the Key West-Havana cables, and will be 0.62 inch in diameter. (Cable dimensions refer to the core diameter before the addition of the outer conductor.)

Manufacture of the cable will demand control of the dimensional tolerances to a greater degree of precision than has been attempted heretofore. This is because the large number of repeaters in circuit make it of great importance to maintain a fine balance between repeater gain and cable loss. Predetermination of the effects of temperature and pressure on cable attenuation will enable this fine balance to be obtained when the cable is at sea-bottom temperature and pressure. Impedance irregularities must also be avoided, since they affect the gain-frequency characteristics of the repeaters.

As is customary in cable practice, special cable armoring will be used near the shore ends, and the various types of armoring are shown in Fig. 5. Type-*A* cable has an armoring consisting of 12 galvanized mild-steel wires, each of 0.3-inch diameter, and is laid in water not deeper than about 300 fathoms; type *AA*, used for the landing, is similar but has an extra layer of armoring. Type *B* is laid in moderate depths and has 18 galvanized mild-steel wires, each of 0.165-inch diameter. Type *D* is laid in all depths greater than about 700 fathoms. It is armored with 24 high-tensile steel wires

of 0.086-inch diameter, each wire being taped; these enable it to be laid and lifted in the deepest water.

7.2 Repeaters

The desirability of a flexible type of housing was referred to in section 3.1. The structure which was finally evolved is a flexible bulge in the cable 8 feet long and 2.9 inches in diameter, tapering, for a distance of about 20 feet at each end, down to the cable diameter. The armor of the cable itself is continued over the repeater housing, but with armor wires added to give complete coverage. To prevent the twisting of the repeater structure in the laying operation, there is a second layer of wires with opposite lay. The repeater itself is enclosed within an 8-foot-long series of cylindrical sections inside the housing.

The structure of the repeater container is shown in Fig. 6. The whole structure is flexible and passes readily over the cable drum and bow sheave without requiring that the ship be stopped. To attain this flexibility the repeater elements within the container are mounted inside a series of lucite (polymethyl-methacrylate) cylinders, successive units being held together by a spring assembly to form an articulated system. Surrounding this series of lucite cylinders is a series of butt-ended steel rings in two layers, the joints between successive rings in the two layers being staggered. Over the rings, and supported by them against collapse at sea-bottom pressure, is an envelope in the form of a long copper tube over which are the protective coatings and armoring wires

The repeater enclosure is terminated at each end with a system of seals, comprising first a glass-metal seal adjacent to the repeater elements, next a plastic seal molded to the cable insulation and, finally, at the extreme ends, a 7-foot-long seal formed within a copper tube which is an extension of the repeater housing. Sea water, in order to penetrate the housing, would therefore have to thread a long, multibarriered path. All of the seals are adapted for the sea-bottom pressures that they may have to withstand. A partially sectioned portion of the seal is shown in Fig. 7, together with further details of the repeater structure.

Fig. 8 is an electrical schematic of the amplifier. The lucite cylinders into which the electric elements will be packaged are indicated in Fig. 6. Excluding the tubes and high-voltage capacitors, 54 components will be accommodated within a volume no greater than that of a 3-inch cube.

The 52 repeaters in each cable will be located at intervals of approximately 37 nautical miles. They will be fed with d-c power originating at each shore end, the power feeding arrangements being described in section 9. Each repeater will produce a drop of 55 volts at a current of 225 milliamperes initially, but after a number of years the current can be increased to a maximum of 245 milliamperes (64 volts per repeater) to offset any deterioration in tube emission.

7.3 Testing Arrangements

Frequencies in the range 167 to 174 kc per second will be used to keep track of the performance and conditions of individual repeaters by means of measurements made from the shore ends. The techniques for doing this have been outlined in earlier articles describing the Key West-Havana System.[4] Briefly, the device used is a quartz crystal resonator shunted across the feedback circuit of the repeater so as to remove feedback effectively over a very narrow frequency band which is different for each repeater. In this narrow band the gain is much higher than at all other frequencies and is very susceptible to changes in tube characteristics. Thus system gain measurements, made at the various crystal frequencies, provide a means for detecting, in each repeater separately, small changes in significant tube parameters which would not be disclosed with normal feedback. At the same time the high gain at resonance creates a series of thermal noise peaks at the crystal frequencies. These can be observed by a narrow-band detector at the receiving end of the cable and will provide a means for locating repeaters which have failed. To accomplish this it is only necessary to note the missing noise peaks, since these are associated with the repeater which has failed and those preceding it. In order to make this test possible, even when the failure is caused by an open-circuit heater, a gas diode is provided in each repeater to by-pass the power-supply current.

7.4 Repair Repeaters

If the cable is damaged during laying or at a later time, it will have to be raised and repaired. After repair the cable length in the repaired section will be greater than before, and this will upset the balance between cable loss and repeater gain. In the deepest water the extra cable length may amount to several miles, and, to compensate for the additional loss, low-gain "repair repeaters" are being provided. One of these will be inserted when a repair is made in deep water.

8. Clarenville-Sydney Mines Section

The frequency bands to be transmitted over the single cable between Newfoundland and Nova Scotia (see Fig. 3) are those used by the British Post Office in most of its shallow-water schemes, except that the bottom frequency band is lowered by 4 kc per second so that the three transatlantic groups can occupy the same frequency band as on the section between Newfoundland and Scotland; this will simplify the frequency-translating equipment.

8.1 SUBMARINE CABLE

The structure and dimensions of the conductors and core of the submarine cable will be identical with those of the cable used between Clarenville and Oban; the cable will have *A*- or *B*-type armoring (Fig. 5). It will, however, be tested to a specification appropriate to the higher frequencies to be transmitted, and taking into consideration the fact that some slight easements are possible because the impedance of the repeaters in this section will approximately match that of the cable.

8.2 LAND CABLE

The land cable will be basically the same as the submarine cable but, being more subject to electrical interference, it will be shielded with layers of soft iron tape applied over the outer conductor. The tape in turn will be protected from corrosion by a polyethylene sheath, over which will be applied jute bedding and armor wires. The cable will be laid in a trench at a depth of approximately 30 inches, where the temperature is expected to have an annual variation of about 35 degrees Fahrenheit and a maximum daily variation of about 2 degrees Fahrenheit. Guard wires for protection of the system against lightning will be laid in the trench above the cable. The two repeaters in the land section will be identical with those in the sea and, according to the terrain determined in the final survey, will be laid in ponds, buried in the ground, or located in small manholes.

8.3 REPEATERS

The mechanical design of the repeaters which will be used in this section is shown in Fig. 9. The electric equipment is mounted in an inner sealed cylinder 4 feet 2 inches long and $7^{3}/_{4}$ inches in diameter, filled with dry nitrogen. This is mounted between brazed-in bulkheads in the pressure-resisting outer housing, which is about 9 feet long and has a maximum diameter of $10^{1}/_{2}$ inches. The glands are polyethylene moldings which are integral with the cable dielectric and which are shrunk on to castellated bosses, previously treated so as to form a bond with the polyethylene. The cable armoring wires are fastened under clamps which transfer the laying tension to the housing; the design of these clamps is adequate to permit of laying the repeaters at ocean depths, although, of course, such strength will be unnecessary for cable-laying operations between Newfoundland and Nova Scotia.

The 16 repeaters in this section will be located approximately 20 nautical miles apart. Electrically, they will be arranged to give 2-way amplification, as shown in Fig. 10. A feature of the design is the inclusion of balanced bridges at each end of the repeater. These not only supplement the directional discrimination in the filters by a minimum of 20 decibels but also contribute substantially to the equalization. The bridges also have the advantage that the intermodulation requirements in the filters are reduced so that small, high-*Q* ferromagnetic-cored coils can be used. Apart from the equalization provided by the directional bridges, the repeater derives most of the necessary gain/frequency characteristic from the 2-terminal feedback network.

There are two 3-stage amplifier units in parallel between common input and output transformers with a single feedback path as shown in Fig. 11. The feedback network will maintain the repeater gain if one amplifier unit becomes inoperative, but the overload point is reduced by 5 decibels under this condition; a faulty component in one amplifier unit cannot affect the other unless it introduces circuit noise. In comparison with a system using single amplifiers, the probable life of each repeater is increased and the probability of early faults on the system is greatly reduced as shown theoretically in the Appendix of an earlier paper.[8]

The wide frequency range to be transmitted over the cable between Clarenville and Sydney Mines will be made practicable only by the use of comparatively modern high-performance tubes with a mutual conductance of 6,000 micromhos. It is well known that the mutual conductance of tubes using conventional cathode cores—nickel with a small content of silicon and magnesium—decreases with time owing to the growth of a resistive interface between this core and the emissive material of the cathode; this interface applies negative feedback to an extent which increases with age. Work in the Post Office Research Laboratories has shown that the formation of an interface can be prevented by the use of pure platinum cathode cores. Cores of this kind, known as "passive" cores, will be used; these increase the difficulties of processing, but result in tubes which should have stable characteristics over very long periods of time.[9]

The heater of each tube requires about 300 milliamperes at 5.5 volts, and the six heaters in each repeater are series-connected; the cathode-anode voltage (90 volts) is derived from a separate resistor carrying the line current. Each group of three heaters is bridged by a device which will short-circuit the group if a heater fails, and thus maintain the line current.

The space afforded by the rigid housing not only permits the complicated circuitry of the British repeaters but also makes it possible to design some of the components on more generous lines than can be fitted into the American flexible housings. For example, the power capacitors use a nonpolar dielectric of mineral oil instead of polar castor oil and are only

subject to about one-third the electric stress. Silvered mica capacitors will be used only where the polarization is less than 10 volts; at all other points the capacitors will be of the sealed oil-impregnated paper type. All components will be manufactured and tested to standards similar to those described in section 3.3.

8.4 Testing Arrangements

It is an advantage of a 2-way cable that, provided some form of frequency translation is possible in each repeater, signals transmitted from one terminal can be returned from the repeaters to the same terminal. In this instance the frequency translation in the repeater is effected, as shown in Fig. 12, by a frequency-doubler associated with filters accepting frequencies in the range 260 to 264 kc (i.e., from Sydney Mines) which are individual to the repeater. Signals at twice these frequencies are returned to the sending terminal and enable an accurate measurement to be made of the transmission level at the output of each repeater at any time.

Pulse-testing equipment will also be provided at each terminal to permit measurements of the overload point of each repeater. The repeaters will be identified on a time base and the frequency translation effected by the overload distortion of the amplifier itself. This test can be carried out in either direction: by direct harmonic production in one direction and by intermodulation of a 2-tone signal in the other direction. It is aimed primarily at determining whether both amplifiers are functioning in each repeater.

9. Power Feed to Repeaters

The arrangements for feeding power to the repeaters on the two sections are generally similar and involve the use of constant-current generators at both terminal stations, series-aiding and arranged so that one end controls the value of the line current; see Fig. 13.

The repeaters on the Clarenville-Oban section will require a total driving voltage of about 3,900 volts initially; this will be increased later to about 4,450 volts, or up to about 4,700 volts if it is necessary to introduce additional repeaters after repairs. The maximum voltage on the cable will be half of this. For the repeaters on the Clarenville-Sydney Mines section the necessary total driving voltage will be about 2,300 volts and, if necessary, it will be possible to feed this from one end only, since the power capacitors are adequately rated.

The constant-current generators used on the two sections will differ in several respects. Those on the Clarenville-Oban section will derive the constant-current feature by feeding via high-impedance pentode tubes with a mechanical regulator to absorb all but short-term variations. To assist continuity of the line current, the load will be shared by two generators at each end, each generator being capable of taking the full load. Transductor-controlled power units will be used for the Clarenville-Sydney Mines section.

Fig. 14. Cable-laying machinery on HMTS Monarch

Every effort will be made to ensure continuity of the d-c power supply to the cable so as to avoid voltage surges at the repeaters and, in order to assist this the a-c supplies to each power feed unit will be derived via a-c–d-c–a-c machines. These machines will be driven normally from commercial power supply mains, but in the event of failure diesel-driven alternators will be started up automatically. There will be two stages of stand-by:

1. The a-c–d-c–a-c machines will continue to run, driven from the 130-volt battery which energizes the d-c machine.
2. If the commercial power failure is of long duration the stand-by diesel plant will take over.

10. Cable-Laying Arrangements

All the cable will be laid by HMTS *Monarch*. This ship, of 8,056 gross tons, was built for the British Post Office in 1945,[10] and with full oil bunkers can carry between 5,000 and 6,000 tons of cable. (The tons referred to here, and in the paper generally, are long tons of 2,240 pounds.)

The *Monarch* is the only cable ship afloat capable of laying the whole of the deep-water part (about 1,500 nautical miles) of each cable between Newfoundland and Scotland in one operation. From earlier sections of the paper it will be obvious that it is desirable to avoid any sequence of operations which will make it necessary to pick up a cable end and to make a splice in deep water. Such operations will have to be carried out if repairs are necessary after the cable has been laid, but inevitably introduce some risk of the cable kinking; the initial laying will be planned to avoid them. All repeaters will have been jointed into the cable before it is loaded into the ship.

A period of 12 days, during which continuously good weather conditions may be anticipated, is necessary in order to carry out the main operation without undue hazard to the repeatered cable. In the North Atlantic such conditions are unlikely except during the period from mid-May to mid-September, and it will not be practicable to lay both the cables on the main crossing in one summer. It is planned to lay one of these cables during the summer of 1955 and to complete all cable-laying operations in 1956.

The essential parts of the after cable-paying-out machinery are shown in Fig. 14. Although the flexible, built-in repeaters are designed to be handled as part of the cable, it is of course desirable not to bend them to a small radius. New cable drums, approximately 7 feet in diameter, are being fitted on the *Monarch*. This is the largest size that can be accommodated without major structural alterations. Bow and stern cable sheaves will also be made this diameter. Roller guides with a minimum radius of 3 feet 6 inches will replace the existing spider wheels and "spectacle" guides throughout the ship to ensure freedom from sharp bends and an easy run of cable from the tanks during laying. Various devices which proved successful when laying the Key West-Havana cables will be fitted to ensure that the repeaters conform to the curvature of the cable drums and to ease their passage round the drums and at other points.

Three new dynamometers will also be fitted, two forward and one associated with the paying-out aft gear. Seven-foot-diameter sheaves will be used, associated with electrically sensitive pressure cells. The latter will be arranged to operate indicating and recording instruments on deck and in the test room, and will enable the tension on the cable to be closely controlled as it is paid out.

The laying of the cable between Newfoundland and Nova Scotia will present no special problems, but an electrically driven hoist has been fitted over the ship's bows to facilitate handling the rigid repeaters.

11. Connection of Cable System to American, Canadian, and British (and European) Internal Telephone Networks

A description of the cable and radio-relay systems which will be used to extend the transatlantic circuits from Oban to London and from Sydney Mines to New York and Montreal would be outside the scope of this paper and, in any case, systems of the same kind have already been used extensively in the countries concerned. It may be of interest, however, to indicate how the connections will be made. From Oban the transatlantic circuits will be taken to London by carrier cable; there will be two alternative routes, one via Glasgow and the other via Inverness and Aberdeen. In London it will be possible to connect any transatlantic circuit to any one of the existing submarine cable circuits to the continent of Europe, thus providing through cable communication between North America and continental Europe. On the American side a microwave radio-relay system will connect Sydney Mines with Portland, Maine. This type of system, which makes use of line-of-sight transmission between relay stations, has already been installed extensively in the United States as a means of providing long-distance telephone circuits of the same quality as cable circuits. From Portland the circuits will be extended to New York by carrier cable or radio relay. Cable connection to Montreal will be effected either at Sydney Mines or at a point on the radio-relay system between here and the American-Canadian border.

12. Conclusion and Speculation

Barring unforeseen and unexpected delays, 1956 should see the completion of the first transatlantic telephone connection via submarine cable. With the completion of this project, telephone service between the two continents should enter into a new era marked by improved quality of service and reliability and a capacity for growth no longer restricted by the limited capacity of the radio spectrum. The advantages of radio will remain, however: flexibility, the speed with which communications can be established and shifted from route to route, the feature of direct access from one country to another, relatively low cost, etc. These are not inconsiderable advantages and they augur for the continued importance of short-wave radio telephone services.

On the other hand, the new transatlantic cable will by no means represent all that could be done if full advantage were taken of contemporary techniques. The submarine cable art is a conservative one. As Dr. Buckley observed, the laying of a submarine cable, like any other activity on the high seas, must be planned with its unavoidable hazards in mind. Experience over 100 years has shown that when handling deep-water submarine cables on the high seas it is better to be safe than sorry.

But the consequences of this doctrine of caution are equally plain. The submerged repeaters in the 1956 deep-water cable section incorporate tubes whose proven design dates back to 1941 and with a mutual conductance of 1,000 microhms. On the other hand, "conservative" postwar tubes provide mutual conductances of about 5,000 microhms, and tubes having a slightly better performance than this will be used in the cable system between Newfoundland and Nova Scotia under conditions where the consequences of tube failure will be minimized. The integrity of such postwar tubes under the severe and highly specialized conditions of installation and use encountered in submerged repeaters remains to be established. On the other hand, without question cable systems having still greater communication capacity can be realized with such new tubes.

Looking still further ahead, the transistor looms as a development which has the potentialities for making possible long, deep-water submarine cables with much greater communication capacity than can be realized with repeaters employing thermionic tubes. The voltage required by the tubes sets an upper limit on the number of them that can be operated in tandem before the power supply results in voltages on the cable that are beyond the limits of safety. The much lower power drain of the transistor should overcome this obstacle and permit more repeaters to be used and wider frequency bands to be accommodated. Ruggedness, long life, and small size are added attractive features of the transistor which are of not inconsiderable importance to the future development of submarine cables. A transatlantic submarine television cable is a long-range goal worthy of serious study and by no means to be dismissed as impractical of eventual attainment.

◆

Discussion

Oliver E. Buckley (retired) (Maplewood, N. J.): The authors have kindly invited me to open the discussion of the paper, and I welcome the opportunity both because of the great importance of the undertaking described and because of a deep interest I have long had in the subject.

The system described represents, in my view, the most radical and important advance yet undertaken in the old and conservative art of transoceanic cables. One way to measure this advance is the top frequency which can be transmitted. It took more than half a century to go from 1 cycle per second or so of the first transatlantic cable to the 100 cycles per second or so of the continuously loaded telegraph cables. Now it is planned to go in one great step to a top frequency of over 100,000 cycles per second and to transmit a broad band of frequencies to provide 35 or more telephone circuits.

One reason for the traditional conservatism of the cable art is the great cost in time and money of making repairs once a cable is laid. This has put a high premium on ruggedness and simplicity. In this new project, simplicity will be sacrificed to no small degree by incorporating in the cable structure a complicated assembly of electronic gear precisely designed to compensate for the characteristics of the cable over a wide range of frequencies, and there will be not just one such repeater but over 100 of them in the two cables for the Newfoundland-Scotland link. This calls for unprecedented care and precaution to ensure success. It has called for extraordinary devices and for imagining all possible causes of trouble that may show up and inventing means to deal with them.

One method of making such a repeatered cable was proposed in my 1942 Kelvin Lecture (reference 1 of the paper). Repeaters of the type there described, with important improvements subsequently added, will be used in the long and deepsea section of the system. The link to connect Newfoundland and Nova Scotia will employ 2-way repeaters developed by the British Post Office. Experience to date with installations of both types of repeater has demonstrated their practicability.

So radical a venture can only be justified by great value to be gained and that value is indeed very great in the present instance. Though transatlantic telephone service, as it is now provided by short-wave radio telephone systems, has become commonplace, it is still short of the perfection of long-distance overland telephone transmission of the coaxial cable and radio-relay systems. Further, overseas short-wave radio is, on occasion, subject to impairment or complete interruption by magnetic storms. Even when radio circuits are working well, there are not enough channels available in the short-wave spectrum to satisfy the ever-growing demand for public service.

The provision of good wire service across the Atlantic will, I feel sure, lead to greater public demand. This will in turn lead to more cables and I expect cables will become the backbone of transatlantic telephone communication.

Confident as I am of the practicability of repeatered submarine cables, and the need for them, I am equally sure that the present designs are not the ultimate and that still better cables will follow. Just as this first edition of a broad-band transatlantic telephone cable system has been made possible by new materials and techniques originated in the laboratory, so will improvements, many of which are now under way, come into being.

Making the present project a joint undertaking brings to it the products of two similar but different lines of development. This is significant of the spirit that has long characterized co-operation between Bell System engineers and the engineers of the British Post Office. Out of this co-operation will come benefits that will contribute to future progress.

The authors of this paper and all who

participated in the project are to be congratulated, but I think they will prefer to receive their congratulations after the job is done and they can talk about it over a circuit that will bring the speakers on both ends as close together acoustically as if they were in the same room.

Col. Sir A. Stanley Angwin (Commonwealth Telecommunications Board, London, England): Having been greatly interested in the first development of transatlantic telephony by radio and in the first proposals for a submarine telephonic cable, I am pleased to have the opportunity of commenting on the project outlined in this paper. It is most fitting that this example of Anglo-American co-operation in the field of telecommunications should be presented in a joint paper before the British Institution of Electrical Engineers and the AIEE.

This paper, with its picture of the growth of the North Atlantic wireless system and account of the first work on submarine repeaters, is of particular interes to the Institution as a corollary to the 33rd Kelvin Lecture given by Dr. Buckley (reference 1 of the paper), and I gave some indication of what was being done and contemplated in the United Kingdom in my Presidential Address of 1943.[1] (That address was, of course, made with many restrictions as to what could be publicized while the war was in progress.)

The tremendous impetus given to long-distance wireless from 1928 on stimulated the cable interests into consideration of the possibility of long-distance submarine cable telephony. An indication of the progress made is the extension of the bandwidth from that of the first transatlantic cable, 1.5 cycles per second, to 100 cycles per second, on the continuously loaded telegraph cables, and to 144 kc per second on the new telephone cable.

The conclusion has now been reached that the ideal should be the judicious combination of radio and cable for transoceanic conditions. In this particular case, not only will telephony by cable be added to radiotelephony between the United Kingdom, Canada, and the United States, giving a much more efficient service at all times, but the possibility is added of telephony from the United Kingdom to Australia and New Zealand over the cable and the trans-Canada line network and thence by radiotelephony on the Pacific route, thus improving the through telephony service to the antipodes to an extent that it will operate over those periods when it is impossible on the direct radio link. The authors are to be congratulated on presenting details of the design of the cable and estimates of its performance before the work is completed.

I think one of the outstanding factors that may be deduced from this paper is that the mechanical problems which have to be met in this undertaking are more critical than the electrical ones. Fundamentally, the solution of the repeater is similar in the United Kingdom and in the American design; the greater difference is in the housing, one articulated and flexible, the other bulkier and rigid.

There is a feeling of confidence in the design on the electrical side, a confidence inspired by exhaustive research and experiment, without which this great work could not have been undertaken. On the mechanical side, the conditions to be met are less determinate and the risks difficult to cover by a factor of safety; this is, perhaps, the most difficult feature and one to which much thought and trial have been given. Other problems are more intractable: the difficulties of cable laying in the Atlantic at depths down to 2,300 fathoms are touched on in the paper.

There have been many epics in the past of cable laying and cable repairs, from those of the laying of the first transatlantic telegraph cables, and as a more recent example of repairs, the attempt to restore the Porthcurno-Harbour Grace cable in 1944. In this attempt some 36 "drives" were made by the cable ship in a period of 40 days in conditions of fog and storm and other difficulties which prevented successful repairs; indeed restoration was not finally carried out until 1952.

I feel that when the first transatlantic telephone cables have been "well and truly laid" great credit will be due to the seamanship of those who overcome these hazards of nature. I hope this phase of the undertaking will be recorded and in due course brought before the Institution.

REFERENCE

1. INAUGURAL ADDRESS, Col. Sir A. Stanley Angwin. *Proceedings*, Institution of Electrical Engineers, London, England, vol. 91, pt. I, 1944, p. 15.

H. J. Rosenberger (All American Cables & Radio, Inc., New York, N. Y.): In section 3.4 of the paper the statement is made: "The composite central copper conductor consists of a central solid wire surrounded by a single layer of spiralling and abutting tapes carefully formed to fit closely about the wire with a minimum of voids. Such a composite structure has better flexibility and protection against breakage than a solid conductor, and has better a-c and d-c resistance than a stranded-wire conductor of the same outside diameter."

It may be of interest to the authors to know that between 1943 and 1954 my company used approximately 500 nautical miles of solid core cable for cable repair work in depths up to 2,600 fathoms and in various lengths up to 24.5 nautical miles. Approximately 400 nautical miles of this had anhydrex rubber insulation and 100 nautical miles were insulated with a polyethylene compound. There has been no significant difference between the incidence of conductor breaks in this cable and in cable using stranded conductors. This repair cable used a 0.095-inch solid copper conductor insulated to a diameter of about 0.26 inch. It had no coaxial return.

Kenneth S. Wyatt (Phelps Dodge Copper Products Corporation, New York, N. Y.): The large amount of research in different fields, the long and intense effort, and the thoroughness of detail which have gone into the solution of the problem of transatlantic undersea telephone cables command respect and admiration. Once the cable is installed and operating, this paper will become a classic. It and its authors will long be remembered.

The authors point out that future cables will be still more efficient when contemporary techniques are more fully tried and advantage can be taken of them. The authors consider chiefly the repeaters and their components, but I think the efficiency of the cable can be greatly improved also. Better to use more efficient cables and fewer repeaters; in fact, on short runs of 200 nautical miles it is better to use an efficient cable and no repeaters at all. This is now feasible.

One way to design a more efficient cable is obviously to employ an air dielectric with a minimum of solid material spacing the inner from the outer conductor. The button or beaded cable is an example; its mechanical weakness in bending and crushing would render it completely impossible for undersea work; electrically it is undesirable for long lines because each button causes a reflection which is additive. However, by employing a helix made up of flexible polystyrene tapes, a wrap over the helix of polystyrene tapes, and an outer conductor and sheath of aluminum, a highly efficient, mechanically strong, economic cable has been attained. Tests show that such a cable is more than adequate mechanically for the laying operation, for the helix gives continuous support, and the styroflex insulation, being harder than the soft copper or the aluminum conductor, does not flow under the pressures involved. Greater precision of centering is obtained by applying the insulation in tape form rather than by extruding. The pitch of the helix is absolute. The electrical efficiency of such a cable derives from:

1. The lower attenuation in the air dielectric and the lower attenuation in the copper conductor (because the lower capacitance permits the use of a larger copper conductor for the same optimum impedance).
2. The effectively 1-piece construction reduces the noise level to the thermal noise level.
3. The extreme precision of the cable makes for negligible impedance variations and phase distortion.

With regard to the aluminum sheath, it is protected by an extruded jacket of polyvinyl chloride or polyethylene over which the standard armoring and hessian servings are applied.

To prevent flooding of the cable in case of damage, nonreflecting pressure dams are built into the cable as manufactured at intervals of 4 to 6 to the nautical mile. Allowing 115 decibels' total attenuation, made up of a signal input of +20 decibels referred to 1 milliwatt and a signal output of −95 decibels referred to 1 milliwatt, a styroflex cable of only 0.86-inch aluminum sheath inside diameter will carrying 60 voice channels of 4-kc spacing, starting at 12 kc and going up to 252 kc, a distance of 104 nautical miles without repeaters. The economic limit for such a system for civilian purposes would appear to be about 200 nautical miles.

There is a great need for an efficient undersea cable for carrier telephone without repeaters between islands. This is particularly true for defense purposes, where the unproved record and limited experience and possible high maintenance of repeaters are serious matters. I proposed such a solution of the communication problem between islands 100 miles or so apart, with shallow water in between, using land-type styroflex cable with the usual submarine corrosion

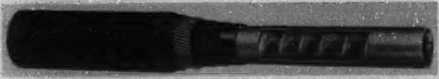

Fig. 15 (right). Shallow-sea styroflex cable. A highly efficient coaxial cable for carrier frequency voice transmission making repeaters unnecessary for distances up to 200 nautical miles. This cable is about 1.2 inches diameter inside the aluminum sheath and will handle 48 voice channels of 4-kc bandwidth for 200 nautical miles. Nonreflecting plugs are inserted every 1,000 feet to prevent flooding in case of damage

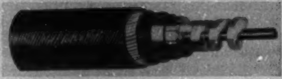

Fig. 16. Deep-sea styroflex cable. A special aluminum alloy armor makes the high-efficiency styroflex cable useful at ocean depths of 30,000 feet. With this cable the number of repeaters on transatlantic telephone circuits may be reduced to one-half or one-third, and possibilities of transatlantic television are thus opened up. Nonreflecting dams are inserted at intervals of 4 to 6 per nautical mile to prevent flooding in case of damage

protection and armoring, to the Canadian Government's Department of Defense Production in May 1952. The cable is shown in Fig. 15.

It is quite feasible, and possibly economical, to span the Atlantic with telephone cable without any submerged repeaters at all, and the authors are doubtless aware of this. In 1952 Halstead published his NARCOM plan[1] of connecting Europe and America with microwave and very high frequency by island-hopping over the North Atlantic, and he brought out the fact that the biggest interisland gap was only 290 nautical miles. I immediately saw that, although Halsted's plan was impracticable because of snow and ice conditions, the Nova Scotia - Newfoundland - Labrador - Greenland - Iceland - Faroe Islands - Shetland Islands-Scotland route was practicable with submarine carrier telephone cable if only the high-efficiency styroflex cable could be reinforced for the deep sea. In June 1952 Felten and Guilleaume of Cologne agreed to undertake a research program to develop such a cable, and within a year a construction was arrived at, after weeding out ideas from both sides, which fulfilled all requirements, including cyclic pressure tests up to 19,000 pounds per square inch. No commercial insulation other than styroflex could have been used. The deep-sea styroflex cable is shown in Fig. 16. A plan utilizing this cable for spanning the Atlantic via the North Atlantic Island Bridge without repeaters was submitted to the U.S. Air Force in June 1953. It carried with it a 5-year guarantee from one of the world's four large submarine cable makers.

The aforegoing discussion is not in any way theoretical. The authors have tested six repeaters on the Havana-Key West run for 4 years. The shallow-sea styroflex cable, it recently came to my attention, has been operating between Norway and Denmark for 14 years without incident. It handles 30 channels of 4-kc spacing (15 in each direction) over a distance of 80 miles. No repeaters are used. At places the water depth is over 2,000 feet. The cable has a lead instead of an aluminum sheath, and long-lay copper tapes under the lead serve as the return conductor.

It is my feeling that the most efficient methods are those with the utmost simplicity. If we can get rid of some or all of these complicated though ingenious submarine repeaters by the simple expedient of increasing the cable efficiency, the transoceanic submarine cable art will be better off. It is of course realized that there are economic limits to this proposal. These proposals in no way detract from the admiration and respect we hold for the repeater development described by the authors.

1. Many Uses for NARCOM Relay System, William Halstead. *Tele-Tech and Electronic Industries*, New York, N. Y., vol. 11, Oct. 1952, pp. 66–67.

J. J. Gilbert (Simplex Wire & Cable Company, Newington, N. H.): The authors of the paper and the eminent engineers who presented discussions have clearly indicated the difficulties and risks involved in the repeatered transatlantic telephone cable. Success will only be attained by adhering closely to the accumulated engineering experience and by use of the utmost care in the manufacture of repeaters and cable. Cable manufacture will be of unprecedented difficulty. Perhaps the most interesting requirement on cable performance is a consequence of the need for impressing potentials to ground of the order of 2,000 volts on the cable insulation in order to supply power to the repeaters. Until comparatively recent years it was considered unsafe to employ much more than 100 volts on long submarine cables. This restriction was based in part on sad experience in applying a high voltage to one of the early transatlantic cables, but there was also the realization that joints in insulation were not as strong electrically as the insulation itself. In the polyethylene cable, jointing has been studied intensively with the aim of obtaining a molecular bond rather than mere physical contact between the surfaces to be joined. The joint is then as strong and as lasting as the insulation itself. To gain still further assurance, the number of joints is reduced to a minimum by insulating the conductors in unusually long lengths.

Assurance of permanence and continuity of insulation and conductors presents many problems to the cable manufacturer; and there are others relating to the need, indicated in the paper, of achieving throughout manufacture predetermined values of electrical characteristics to an unusually high degree of precision and uniformity.

I would like to add to the tribute that has been paid to Dr. Buckley. All who have had contact with him in submarine cable development appreciate the inspiration of his leadership and the skill with which he placed this work on a firm foundation.

Mervin J. Kelly, Sir Gordon Radley, G. W. Gilman, and **R. J. Halsey:** We have been honored by the discussions from Sir Stanley Angwin and Dr. Oliver E. Buckley to whom the submarine cable art has owed so much for so many years. We express our thanks for their comments on the background of this project and for their confidence in its success. When the first transatlantic cable has been "well and truly laid," a complete discussion of the problems can certainly be expected.

Regarding Mr. Rosenberger's comments on the make-up of the center conductor, it is generally agreed that a solid conductor would be preferable for transmission reasons. Modern brazing techniques and methods of manufacture and inspection of the center conductor increase the likelihood of obtaining a mechanically dependable solid conductor. In the past, the use of soft soldered joints and the possibility of hidden inclusions in the copper have led to the choice of a composite structure and the present project has been based on designs which have proved their reliability by long usage.

Mr. Wyatt's comments can be divided into suggestions on the cable make-up and suggestions concerning the optimum cable route. With regard to his suggestion that nonrepeatered cables with partially air-spaced dielectric are best for distances less than 200 miles, the British Post Office has had 8 years' experience of such air-spaced polythene cable in the North Sea, providing, e.g., 84 circuits over a distance of 82 nautical miles. While these cables have been quite satisfactory, this type will not be used in the future because experience has proved that the circuits can safely be provided at much less cost by smaller diameter solid dielectric cables with repeaters.

On the transatlantic cable make-up, many different designs were studied. The main advantage of the design Mr. Wyatt describes is its lower dielectric constant which reduces attenuation for a given diameter. From Mr. Wyatt's figures, a 0.86-inch styroflex cable would have an attenuation of about 1.11 decibels per nautical mile at 252 kc per second, whereas a corresponding solid polyethylene dielectric cable of this size would have about 1.45 decibels per nautical mile at that frequency. On this basis, the increase in repeater spacing made possible by the proposed cable design would be about 30 per cent. If a much larger diameter styroflex cable were practicable for use in deep water, the ratio of the repeater spacing with such a cable to that with the present 0.62-inch solid polyethylene dielectric cable might be of the order of 2 or 3 to 1, as mentioned by Mr. Wyatt. In any case, the decision on the type of cable for this installation was made on the basis of proven integrity over a long period of usage and the solid dielectric cable was the only one with such a history in deep water.

On the matter of the optimum route, everyone interested in transatlantic cables has looked at a northern route—Shetlands, Faroes, Iceland, Greenland, Labrador (or Newfoundland)—with interest, and a number of detailed plans have been investigated, the first following the failure of the 1858 cable. The maximum distance between landings would be less than 1,000 nautical miles and the eastern part of the route would be easy. The western sections, however, would be difficult to lay and maintain in view of the ice conditions. Cable could usually be laid between Greenland and Newfoundland only in the months of September, October, and November when the days are short and the weather is poor, and year-round maintenance would only be possible if an ice-breaking cable ship were used. There is also considerable hazard from grounding icebergs. For a first transatlantic telephone cable, therefore, this route did not appear very safe.

We are also grateful for the comments by Mr. Gilbert who took a considerable part in the effort during the years before this project was launched.

A New Full-Wave Magnetic Amplifier Output Stage

P. W. BARNHART
ASSOCIATE MEMBER AIEE

ol. 74
. 1
955

THOSE concerned with the development of high-performance magnetic amplifier servo systems have long recognized the need for an output stage which would produce a full-wave current output into a servomotor and still retain the two inherent advantages, namely, the high speed of response and demodulation of the half-wave amplifier. In this paper a new concept in full-wave push-pull output stages is presented which fulfills this need. Test data are given to show its operation in an actual system.

As noted in an earlier paper on the half-wave bridge type magnetic amplifier,[1] the half-wave input to the motor contains a fundamental component which provides considerable torque. However, it is less than rated torque. The system designer must bear this in mind when he chooses a motor, because he will not be able to produce full-torque output from the motor even when using a shunt capacitor across the control phase windings. In general, the d-c component causes some loss of torque, about 15 per cent, but saturation effects vary widely from motor to motor. In many instrument servos this problem is not critical, but in other systems a better utilization of the servomotor is desirable.

While a conventional full-wave magnetic amplifier will provide the desired type of control current for the motor, it does not provide the two inherent advantages gained by using half-wave amplifier techniques, namely, speed of response and inherent demodulation. While much has been claimed about the speed of response of full-wave amplifiers with the relatively low gains used in servo systems, no one has produced a control system with such an amplifier that demonstrates the response of similar systems using half-wave amplifiers. The use of inherent demodulation characteristics to provide system compensation, as demonstrated by the U. S. Naval Ordnance Laboratory,[2] is not readily available when full-wave amplifiers are used. The use of compensation with full-wave amplifiers is usually concerned with improving amplifier response, not system response. Neither of these types of amplifier is the complete answer in the case where it is desirable to have a high-performance control system and utilize the servomotor to a maximum.

General Solution of the Problem

The ideal solution in this case is a half-wave amplifier in which the output can be converted to a full-wave voltage applied to the load. A circuit which will store information about the output of the half-wave stage into the load and produce the same output into the load on the next half-cycle will solve this problem. It must produce a phase-sensitive output with a minimum of d-c component, or a polarity-sensitive direct current.

The circuit which will most easily accomplish this task is simply another half-wave magnetic amplifier stage slaved to the output stage. A circuit to achieve this effect in single-ended amplifiers has been described by Lord.[3] Fig. 1 shows diagrammatically how such a "slave" stage operates. The input to the normal half-wave output stage is amplified and fed to the load. This amplified signal is also used as an input to the slave half-wave stage which, in turn, produces a like output to the load on the next half-cycle. The method of utilizing the output of the driver stage to control the slave stage and thus produce the desired full-wave output is very simple and can be accomplished in several ways.

Slave Stage Control in the Load Windings

The first method investigated was that of introducing control into the cores of the slave stage via its load windings. It had been noted early in the work on half-wave amplifiers that an alternating voltage across the load during the reset half-cycle of the output stage has a tendency to produce control on that stage if the rectifiers did not present a very high impedance. Thus, if the load on the amplifier were reactive, as with a servomotor, and the rectifiers did not have high back impedances (or were shunted for reset), the output stage would receive control from the reactive voltage across the motor and continue to produce output for several cycles after the signal was reduced to zero. Reference to Fig. 2 will show how this control is affected. This is the load circuit of a simple half-wave bridge output stage during the reset half-cycle when there was an output the preceding half-cycle. The voltage appearing across the load, e_0, and the line voltage e_L have the polarities shown. Instead of each load winding and its respective rectifier now having the voltage $e_L/2$ applied to it (as with a resistive load), *ab* and *ef* now have $(e_L+e_0)/2$ applied to them and *bc* and *de* have $(e_L-e_0)/2$ applied. If the rectifiers allow leakage current to flow, part of this voltage will be utilized in

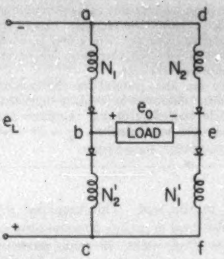

Fig. 2. Half-wave bridge load circuit during reset half-cycle

changing flux in the cores, and control will be established to produce output the next half-cycle independent of any other signal applied to other windings. It will be noted that this control will produce on the next half-cycle an output current in such a direction as to reverse the polarity on the load. If the load polarity, as shown in Fig. 2, were produced by a half-wave bridge magnetic amplifier connected at *b* and *e*, the circuit of Fig. 2 would be a slave stage producing an alternating current with no other control signal. Care must be taken that the roles of the slave and driver stage are not reversed on the next half-cycle. The driver stage must have rectifiers with very high impedances so that feedback from the slave stage will not control it and increase the response times. To produce an alternating voltage across the load with no direct component, it is necessary that the back leakage of the slave stage rectifiers be reduced until the control injected will fire its cores exactly 180 degrees after the respective cores of the driver stage.

Experimental results with a full-wave bridge amplifier indicate that it is impractical to use this method of control. To get the required amount of leakage to eliminate the d-c component, it was necessary to shunt the rectifiers or to remove plates to such a level that the reset windings had to be reversed to maintain equal quiescent currents in both stages. Under such conditions, the slave stage gain was nonlinear and the desired zero direct component could only be obtained at one level. No further work was done at this point to determine whether different combinations of load or reset turns would produce satisfactory output stage with the slave stage controlled in the load windings. Instead, work was shifted to investigation of control through a different winding.

The Use of Separate Control Windings

Possibly the next approach would appear to be adding a control winding to the slave stage and connecting it directly across the load. This method of control was not used, however, because earlier experience had shown that closed loops in half-wave circuits where direct current may flow will, in most cases, decrease the speed of response markedly. Instead, the control windings were connected in series with the load.

This type of connection is peculiarly adapted to the control of a half-wave stage. It is known, and has been proved analytically,[4,5] that the voltage gain of a half-wave amplifier increases as the number of control turns decreases. To achieve this high gain by lowering the control turns, the control source must have a low driving impedance. It must be able to supply the high currents which will flow when maintaining a flux-changing voltage across a low number of control windings. The driver stage designed to drive the motor load can supply these high currents easily. Since only a small voltage is required across the load windings to obtain an output from this high gain slave stage equal to the driver stage output, very little of the load voltage is lost. At the same time, voltages induced into the slave stage control windings under signal conditions are extremely small. This unique combination of properties produces an excellent method of slave stage control. While this type of control could be used in conjunction with the type previously discussed, its use alone is so straightforward and comparatively simple that the other method is probably only of academic interest.

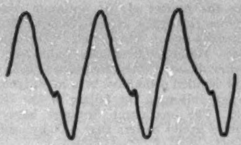

Fig. 4. Full voltage across motor driven by full-wave bridge slave circuit

Fig. 3 shows a full-wave bridge amplifier with control windings on the slave stage; only the load and control windings are shown. Cores 1 and 2 are in the driver stage. It will be noted that the sense of the slave stage control windings is very important. As shown in Fig. 3, the circuit will produce a phase-reversible a-c output. If these windings are reversed, the output will become polarity-reversible direct current. Thus, just as the half-wave bridge, this circuit can be used in conjunction with either a-c or d-c loads. If this amplifier is used to supply direct current, care must be taken that the rectifiers used have a high reverse impedance to prevent control through the load windings which would produce an a-c component.

Using the circuit of Fig. 3 connected for an a-c load, it is possible to apply somewhat more than rated voltage to commonly used 400-cycle-per-second 2-phase servomotors with the control winding in parallel (57.5-volt connection).

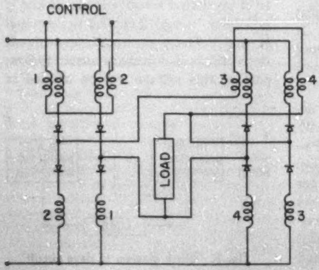

Fig. 3. (left). Full-wave bridge slave circuit for a-c load

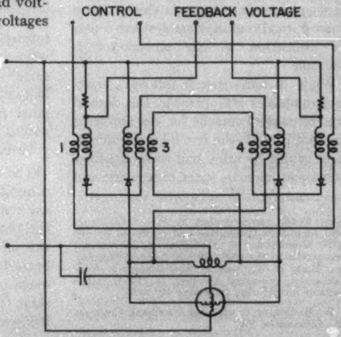

Fig. 5 (right). Full-wave slave circuit with output transformer

The full output wave form across the motor is shown in Fig. 4. The voltage gain of the output stage is about 150.

One disadvantage of the bridge circuit operated directly on a line is that it will not develop full-line voltage across the load. Until recently, it has been somewhat difficult to obtain standard 2-phase servomotors with control windings that could be paralleled for 57.5-volt operation, especially at 60 cycles. With a full-wave bridge it is possible to use a small transformer to increase the motor voltage (even high enough for motors designed for plate-to-plate operation) without danger of saturating the transformer. By center-tapping the transformer, the bridge windings can be simplified to single windings and a full-wave push-pull amplifier with differential output is obtained.

Such an output circuit is shown in Fig. 5. This output transformer can be a simple center-tapped autotransformer if the motor has a 115-volt control winding. It may be tapped in a different manner for motors with higher or lower voltage control windings. If the motor itself has two 57.5-windings or a center-tapped 115-volt winding, it may be used in the circuit of Fig. 5 in the place of the transformer. It is necessary, in this case, to put a capacity across the motor windings to obtain full output. Also the quiescent currents must be set at a level that will not cause excess temperature rise in the motor at zero signal. The slave stage control windings of Fig. 5 are differentially connected. This gives improved linearity over the use of individually controlled cores, the latter case producing interference with reset windings. The number of these control windings used on both 400- and 60-cycle units has been less than 10. The series resistors in the driver stage are used to provide a direct voltage for feedback compensation purposes.[2]

Test Results and Conclusions

The performance of this amplifier in a servo system has been very good. Two half-wave bridge amplifier stages of the type shown in Fig. 2 are used as a preamplifier for the amplifier of Fig. 5 with a 400-cycle motor load (*BuOrd Mk. 8*). With a 10,000-ohm input impedance the open-loop voltage gain is over 700. When the loop is closed with a 50 to 1 gear ratio and using a feedback network providing simple lead compensation, the resulting bandwidth is 17 cycles per second and the velocity constant is 200 degrees per second per degree error. The natural frequency of the mechanical system without compensation is only about 3.5 cycles per second. Lead-lag compensation as used with half-wave amplifiers can also be easily applied.[6]

This circuit has proved to be an excellent output stage for high-performance control amplifiers by combining the advantages of half-wave and full-wave circuitry. However, the use of this type of slave stage control is not limited to driving a-c motors. Controlling phase-sensitive saturable reactors, d-c servomotors, and rotating electromechanical amplifiers are only a few of the other applications which are immediately brought to mind.

Switching Transistors Used as a Substitute for Mechanical Low-Level Choppers

A. P. KRUPER
NONMEMBER AIEE

ONE of the interesting possibilities of using transistors as switches would be to replace mechanical vibrators or choppers in the input of d-c amplifiers. The ability of transistor switches to function with emitter-collector voltages of the order of 1 millivolt or less led to a further investigation of transistor-switching behavior at these very low levels. Peculiarities of circuits utilizing transistors as switches at these low levels are discussed and possible methods of compensating for these peculiarities are presented. Effects of temperature on behavior were also investigated and it was found that, by suitably matching pairs of transistors, the effects of temperature from −50 to +90 degrees centigrade (C) were practically negligible for germanium transistors.

Present Choppers

The chopper applications to be discussed are essentially of the type illustrated in Fig. 1. Here the problem is to amplify a low-level d-c signal in a manner which is free of the drift and instability of d-c amplifiers. A mechanical SPDT switch alternately connects the d-c signal to either side of the center-tapped input transformer producing a square-wave a-c output signal which is easily amplified by the a-c amplifier. A-c amplifiers having good linearity and stability are much easier to design than d-c amplifiers. The output of the a-c amplifier is then rectified, e.g., by a synchronous rectifier and read on the d-c meter. The input chopper can be a motor-driven switch or, what is more common today, a magnetically driven vibrator switch.

In another version of this same circuit, which is perhaps more common for commercial and military applications, the d-c input signal is derived from an error signal which is reduced to a minimum or zero by electric means actuated by an a-c motor driven directly by the output of the a-c amplifier. The direction of rotation of this motor is determined by the phase of

A. P. Kruper is with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

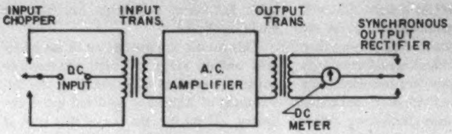

Fig. 1. Schematic representation of chopper-type d-c amplifier

the a-c output signal. It will be observed that, if the polarity of the input d-c error signal is reversed, the a-c signal produced undergoes a 180-degree phase reversal.

Transistor Choppers

The remainder of this paper will concern the properties of this input choppers. Fig. 2 shows a schematic of an electromagnetically driven mechanical vibrator chopper and a direct substitution of the vibrator switch contacts with switching transistors. The mechanical chopper is energized from the line voltage. The switch arm alternately swings from one contact to the other in phase relationship with the line voltage. In Fig. 2(B) an arrangement is illustrated where each switch contact of Fig. 2(A) has been replaced by a transistor switch and each transistor switch is opened or closed by means of an a-c signal applied between the base and collector. However, if the output of the transistor chopper were to be examined, it would be observed that, although it behaved very much like the mechanical chopper, with zero d-c input signal, an a-c signal was still produced in the output. The a-c signal is produced by a small voltage developed by the transistor, of the order of 1 or 2 millivolts, when the switch is closed. This might be likened to the condition which would exist in the vibrator if the switch contacts were of dissimilar metals such that a thermal electromotive force would be produced at the contact points every time the switch was closed. Of course, vibrator manufacturers take great pains to keep these contact electromotive forces to a minimum. The source of this potential in the transistor chopper and possible methods of compensating for it will be investigated in the following sections.

Transistor Characteristics

Fig. 3 shows the family of characteristic curves of a transistor when operated as a switch. As pointed out by Dr. Bright,[1] the transistor does not behave as a perfect switch, a fact which is shown by the displacement of the point *P* from the origin. The voltage appearing across the load of the transistor chopper in Fig. 2 with zero input signal is approximately V_P. The operation of the transistor chopper may be analyzed by considering the load line as the impedance of one-half of the transformer input winding and the d-c input signal voltage as the supply voltage. At this point only the operation of one of the transistors will be considered. As the input d-c signal voltage is decreased, the load line moves downwards towards the origin causing the a-c output voltage to decrease in amplitude. Finally, at some input voltage slightly greater than V_P, the load line passes through *P* and no alternating voltage is produced in the load. Now if the input d-c signal voltage is further decreased until it becomes zero, the load line passes through the origin *O* and an alternating voltage is again developed across the load. The amplitude of this alternating voltage is approximately equal to V_P but is reversed in phase 180 degrees from the alternating voltage which was produced when the load line was above *P*. If the polarity of the d-c input is now changed and increased in magnitude, the load line continues to move downward producing an a-c signal of increasing amplitude. Hence, it is seen that an a-c signal is obtained whose amplitude is proportional to the magnitude of the d-c input and whose phase is a function of the polarity of the d-c input.

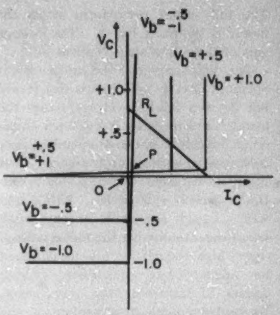

Fig. 3. Characteristics of n-p-n switching transistor at low levels

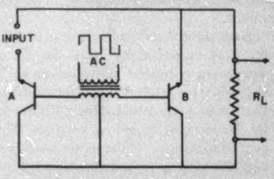

Fig. 4. Improved transistor chopper circuit

A word might be mentioned at this point about the order of magnitude of the coordinates V_P and I_P for the normal and inverted connections. Values between 10 and 40 millivolts have been obtained for the normal connection of typical n-p-n units, while values for the inverted connection for the same transistors ranged from 0.5 to 1.5 millivolts. Currents of the order of 40 microamperes in the normal connection were reduced to 1 microampere in the inverted connection at room temperature. This clearly points out the superiority of the inverted connection for low-level chopper applications.

Circuit Considerations

Whereas the transistor chopper illustrated in Fig. 2 suffered from the effects of this residual voltage V_P, or feed-

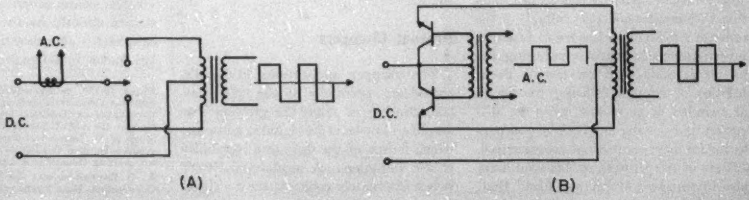

Fig. 2. Input chopper circuits showing (A) conventional mechanical vibrator, and (B) substitution of switching transistors for mechanical contacts

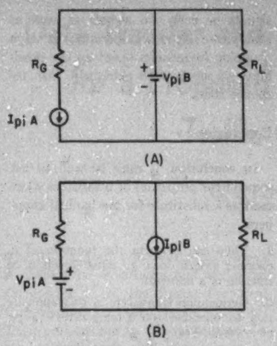

Fig. 5. Equivalent circuits of transistor chopper shown in Fig. 4

through voltage as it is sometimes called, Fig. 4 shows a circuit in which these voltages from the two transistors tend to cancel each other providing a nearly ideal low-level chopper. The input is applied as shown and, on one half-cycle of the chopping frequency, transistor *B* is open and transistor *A* is closed, completing the circuit from the input through *A* and to the load R_L. On the alternate half-cycle, transistor *A* is open and transistor *B* is closed, effectively short-circuiting the load R_L. Transistors *A* and *B* are shown in the inverted connection and are preferably driven by a square wave of approximately 1 volt of amplitude.

In this particular circuit, the maximum input voltage is limited to the same order of magnitude as the base driving voltage if the transistors are to operate satisfactorily as switches. This is ordinarily no objection in low-level operation where the input signal always remains in the millivolt region such as when operating with thermocouple input. If it is desired to work with higher input voltages and still to go down into the low-level regions, then the back-to-back transistor arrangement mentioned in reference 1 can be used in place of *A* and *B*, which would then require four transistors instead of two. Such a circuit could be used to convert voltages of the order of 50 volts of direct current of either polarity to alternating current, such as is required for analogue computers. Extremely good linearity of conversion to a fraction of a per cent can be achieved in this application.

Fig. 5 shows the equivalent circuit for the low-level chopper during alternate half-cycles. During the first half of the cycle, as shown in Fig. 5(A), transistor *B* is conducting and is represented by a battery V_{PiB} of the polarity shown directly across the load, and the transistor *A* is open and is represented by a current generator I_{PiA} in series with the input source R_G. Here the voltage developed across the load is the voltage caused by transistor *B*, and the effect of the current from *A* is negligible. During the alternate half-cycle, transistor *A* is closed and is now represented by a battery in series with the input source R_G. Transistor *B* is open and is shown as a current source across the load R_L. If R_G is small, such as would be the case with a thermocouple input, the voltage across the load is essentially the input voltage in series with V_{PiA}, and the effect of I_{PiB} is negligible. For the condition of no d-c input signal voltage, the voltages from transistors *A* and *B* appear across the load during alternate half-cycles but in the same direction and, hence, produce a constant direct voltage rather than an alternating voltage across the load, if they were initially selected to have equal values of V_P.

The effect of I_{Pi} was stated as being negligible due to the fact that its magnitude was small. This might not be the case for germanium transistors at high temperatures and, hence, R_G should be kept as small as possible. Alternately, it is possible to insert a series resistance equal to R_G in the leg of transistor *B* such that the voltage drops caused by the I_{Pi}'s are equal. In this manner the equivalent circuits for both halves of the cycle become identical providing nearly perfect compensation.

Temperature Effects

Since the problem of compensating for the feed-through voltage V_{Pi} by matching transistors has been mentioned, it might be of interest to examine some typical values obtained for V_{Pi} for six unselected experimental Westinghouse n-p-n germanium transistors. Fig. 6 shows a plot of V_{Pi} as a function of temperature for these transistors. It will be seen that the maximum spread in this value is about 1 millivolt over a temperature range of −50 to +90 C. Also, it will be noted that four of the six units tested all fell within a region where the spread was about 0.1 millivolt over this same temperature range. It would not be difficult to select two transistors, e.g., numbers 1 and 5 which would match to within about 25 microvolts of each other over this temperature range. Thus, it is

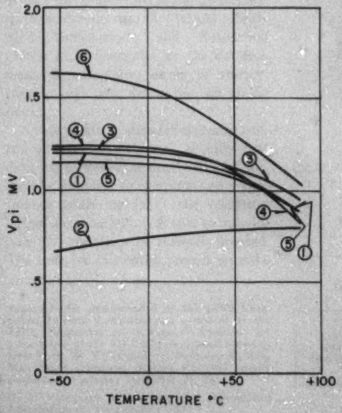

Fig. 6 (left). Variation of V_{Pi} as a function of temperature for six randomly selected n-p-n junction transistors

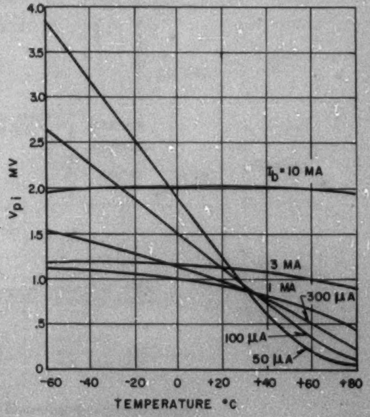
Fig. 7 (right). Variation of V_{Pi} of a typical n-p-n transistor as a function of temperature and base drive



seen that it would be possible to use these two transistors in a transistor chopper circuit and have less than 25 microvolts' a-c signal output produced over a temperature range of −50 to +90 C if zero-input signal voltage were applied.

Similar measurements on the normal connection for the same six transistors exhibited a spread of from 10 to 40 millivolts of the feed-through voltage V_{Pn} and the best compensation which might be achieved over the same temperature range would be about 2 millivolts at best. This, again, points out the superior advantages of the inverted connection.

The curves in Fig. 6 show the variation of V_{Pt} with temperature with a constant base drive of about 3 milliamperes. Fig. 7 shows a plot of the variation of V_{Pt} with temperature as a function of the base drive current for a typical transistor. It should be noted that, as the base current is increased, the curves become more nearly horizontal. This provides a convenient means of matching the feed-through characteristics of pairs of transistors, since a series resistor in the base circuit of each transistor can be adjusted to provide the desired base current. Alternately, since the curves are so nearly horizontal, it is possible in certain applications to buck out this voltage with a fixed potential.

Advantages of Transistor Choppers

Now that the behavior of a transistor chopper circuit has been reviewed and it appears that it is possible to operate such a device at levels of 1/10th millivolt and less over considerable temperature variations, other advantages of transistors for this application should be mentioned.

One of their big advantages over mechanical choppers is that they are inertialess devices. As such, they can be operated at any line frequency, or even varying frequency, without loss in performance. They have practically zero phase shift up to about 10 kc as contrasted to appreciable phase shifts from 30 to as high as 90 degrees for mechanical choppers. Mechanical choppers, on the other hand, are usually designed for a specific frequency or narrow range of frequencies because of problems associated with designing the mechanical vibrating reed, and the phase shift also varies with chopping frequency.

Being inertialess devices of very small mass, transistors are practically immune to shock and vibration and, hence, are ideal choppers for military and guided missile applications. Actual tests under all environmental and temperature conditions have not been completed but are in the process of being investigated.

Although nothing has been said about other than mechanical choppers, it should be pointed out that other modulators such as diode-bridge modulators, etc., can be replaced by the transistor choppers with corresponding gain in sensitivity at low levels.

The fact that the transistor chopper can be operated at frequencies up to hundreds of kilocycles makes it possible to use it as a carrier for rapidly varying d-c signals or even a-c signals as well as steady d-c signals. Operation at high chopping frequencies opens up the possibility of servos with extremely fast response times.

Conclusion

In conclusion, it may be well to list some of the properties of transistors when used as a substitute for mechanical choppers.

1. They can perform the function of a chopper switch down to signal levels of a fraction of a millivolt.
2. Germanium transistors in this application are operable over a temperature range of −50 to +90 C.
3. They are synchronous with line frequency and have practically zero phase shift up to the kilocycle ranges.
4. They are low-impedance devices and should, therefore, be used with low-impedance sources.
5. They are small in size and light in weight.
6. They are nonmicrophonic and insensitive to shock.
7. They should have inherently long life as contrasted to mechanical choppers.
8. They are not subject to contact pitting and burning as occurs in mechanical choppers.
9. They have a dynamic range of greater than 110 decibels.

Data Transfer and Display Equipment for a Proposed System of Air Traffic Control

G. E. FENIMORE
NONMEMBER AIEE

IN 1947, a group representing all phases of the aviation industry met as Special Committee 31 of the Radio Technical Commission for Aeronautics (RTCA). Their purpose was to bring order out of a chaos where many different systems of air navigation and air traffic control were being proposed and developed to satisfy the same need. This group evaluated the existing and proposed systems and formulated a long-range plan for orderly progress toward the development of a common system to serve all nontactical military air traffic and all civilian aircraft.

The *SC-31* report which the group produced outlined the broad general requirements for an automatic air traffic control system using information transmitted over land line teletypewriter circuits and ground-to-air radio circuits.[1] The use of several special-purpose computers to process the data acquired was also recommended in the report.

In 1948, the Air Navigation Development Board was established to administer funds which were appropriated by Congress to develop the common system recommended by the RTCA. A study was made of the use of computers for handling air traffic data, and in 1950 a project was established at the Civil Aeronautics Administration (CAA) Technical Development and Evaluation Center in Indianapolis for the "development of automatic means of storing, transferring, and displaying air traffic data.

An automatic system for air traffic control on a nation-wide scale requires that data for numerous remotely located aircraft be supplied to computers on a continuous basis and that the computer output be promptly available to individuals who may also be remotely located. The time for this entire process must be short enough, so that air traffic controllers concerned with a predicted confliction between aircraft can be aware of the difficulty in time to reassign airways or altitudes to avoid an accident. Such a system could be likened to a computer having its input and output devices remotely located from the memory and computation equipment.

It was determined that basic building blocks for the system could be represented by a fully automatic teletypewriter switching system for communications, magnetic-drum storage equipment for memory and processing of flight plan information, and automatic display boards for rapid data display and transfer. The proposed organization of this system is shown in Fig. 1, which illustrates how the equipment may be used for handling both flight plan data and weather information.

A flight plan includes such information as aircraft identity, departure airport, time of departure, destination, cruising speed, and a proposed timetable for the flight. Data in the form of incoming flight plans may be fed into the system from a remote station connected to the automatic teletypewriter switching center. Such remote stations would be located at major airports and at CAA communication stations where flight plans are normally filed. This teletypewriter message would be directed by the automatic switching center to the magnetic drum equipment for storage and would be displayed in front of an air traffic controller for approval at the local display board. The traffic controller would check the proposed flight plan against other flights for conflicts and would issue a clearance for the flight. In the first implementation of the system, this check would be made by the traffic controller, but an ultimate system may include a computer to search for conflicts automatically, using data stored on the drum. Clearances would be automatically directed to the remote display at the departure airport tower.

Fig. 1. Block diagram of proposed system

While the flight is in progress, information must be transferred from one traffic control center to another along the route. Controllers are in contact with the flight by radio and may need to alter schedules or clearances from time to time because of delays or new flights entering the area. Drum information must be kept current and traffic controllers must have current schedules available at all times. These

data would be provided by the proposed automatic system.

On the right-hand side of the diagram, the same teletype switching center and magnetic-drum storage equipment are involved in a proposed system of collecting, storing, and distributing aviation weather information. Incoming weather reports such as the Cleveland weather, for example, pass via the switching center to the drum where they are stored and automatically sent to the program printer at locations requiring this weather information on a continuous basis. Stations which need the Cleveland weather occasionally would be able to send a message to the drum requesting this information and to receive in reply the desired weather report. Having discussed the proposed system operation, it will be necessary to take a closer look at some of the elements.

Automatic Teletypewriter Switching Equipment

The fully automatic teletypewriter switching equipment to be used is a modified version of the Western Electric type-*81D1* system, described in the literature.[2,3]

Magnetic-Drum Message Storage and Processing Equipment

The use of magnetic drums for information storage is well known in the computer art. The magnetic-drum message storage and processing equipment associated with this system was built by Remington Rand Inc., and is now operating on a test basis at the CAA Technical Development and Evaluation Center in Indianapolis. This equipment has been described in references 4 through 6.

A general view of the storage and processing equipment is shown in Fig. 2. Fig. 3 illustrates the magnetic drum which is capable of storing 2,000 flight plans in the form of individual teletypewriter messages. The total information storage capacity of the drum is 316,250 characters or 1,581,250 bits. When a request for information has been received by this equipment, the time required for searching through the drum storage and preparing the desired message for replay is less than 1/2 second.

Data Transfer and Display Equipment

The third element of this information processing system to be described in detail is the data transfer and display equipment. This equipment has been developed to satisfy the following basic requirements:

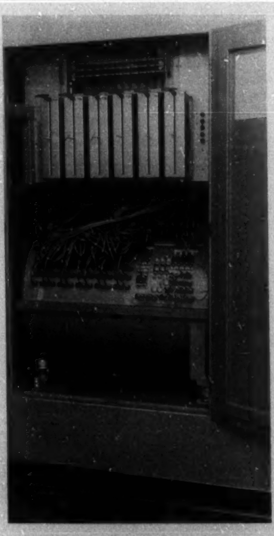

Fig. 3. Magnetic-drum cabinet

1. Display of information: To display on a board in front of air traffic controllers information such as the identity of an aircraft, its altitude, speed, destination, and a timetable of its route. This information constitutes the flight plan.
2. Ability to communicate with the magnetic-drum equipment: To permit an operator to send a request message to the magnetic-drum storage equipment asking for the flight plan of any aircraft and display automatically the reply from the drum on his board.
3. Ability to change individual characters or the sequence of display information: To permit the operator by simple push-button manipulation to rearrange the order in which various flight plans appear on his board or to change individual characters of the displayed information.
4. Rapid data transfer between display boards: To permit the operator by simply push-button manipulation to transfer information appearing on his board to another similar board, or to compose and send automatically a message containing the displayed information to the magnetic-drum equipment.

Specifications for equipment to satisfy these requirements, and others which will be described later, were written by the Technical Development and Evaluation Center of the CAA. The Union Switch and Signal Division of Westinghouse Air Brake Company, has developed and produced two display boards for evaluation in air traffic control systems.

Indicators

The basic building block of the display boards is a small electromechanical indicator which can display any one of 64 different letters, figures, or symbols in a small window at one end. Each indicator is approximately 11 inches long,

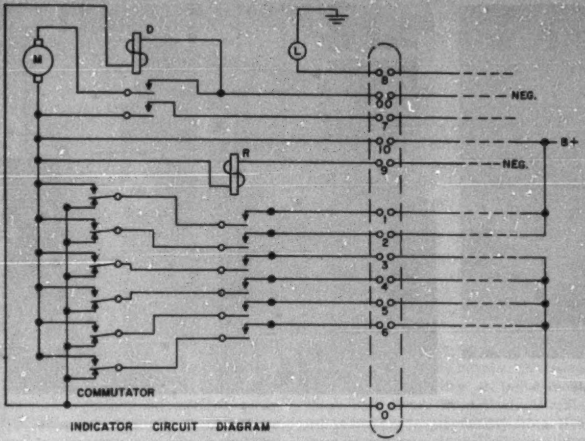

Fig. 5. Indicator circuit diagram

$1^3/_4$ inches high, and 5/8 inches wide and is capable of changing the character displayed to any other character within $1^1/_2$ seconds. A number of such indicators can be mounted in a console and a single row can be energized to spell out information. Since the magnetic-drum storage equipment and the automatic switching center both handle information in the form of teletypewriter code, the indicators and display equipment have been designed to speak the common language.

Fig. 4 is an inside view of one of these indicators. At the rear is a moulded plug for making the electric connections. These connections include six code wires for determining which character shall be positioned, and several wires for power, lighting, and control. Near the plug is a relay which, when energized, will make connections to the six code wires. At the center is a small motor which drives the sprocket and endless belt assembly during positioning. A detent magnet acting upon the rear sprocket insures accurate positioning of each character in the front window and controls power to the motor. On each sprocket wheel is a code segment which together with the brushes shown on the upper half of the indicator provide a homing circuit with the six code wires for positioning a desired character.

An electrical diagram of the indicator is shown in Fig. 5. For a character such as the letter *A* to be positioned, a direct voltage must be applied to wires 1 and 2 while wires 3, 4, 5, and 6 are connected together, as shown in the diagram. This corresponds to the teletypewriter code for *A* which is two marks and three spaces in the 5-unit system. Absence of voltage on the sixth wire indicates that this is a lower case character. Since a 6-wire system can provide 64 combinations, the indicator is capable of displaying 64 unique characters in its window. The characters selected for this model are 26 letters, 10 digits, and the weather symbols commonly used in the CAA teletypewriter circuits.

In addition to the ability to display various characters, the indicator acts as a memory device in that it is also capable of reading out the electrical code for the character being displayed. By energizing wires 9 and 10, this read-out function can be accomplished without disturbing the displayed information. Under this condition if the indicator is at rest with the character *A* being displayed, wires 1 and 2 will have voltage on them, while 3, 4, 5, and 6 will be connected together. With two indicators connected back to back, one indicator can be energized to read out its character and the other indicator will be driven until it is displaying the same character as the first. This principle is utilized for transferring information from one row of indicators to another in the console.

Manual Operation of the Display

The display console is shown in Fig. 6. The sloping panel can accommodate 660 indicators arranged in 11 rows of 60 each. Data concerning one flight plan normally would be displayed in one row. Certain buttons and lamps are associated with each individual row and these are arranged in groups along the left side of the indicators, see Fig. 7. These buttons provide normal control for the following operations:

1. Data in any row can be transferred to any vacant row.
2. Data can be erased from any row.

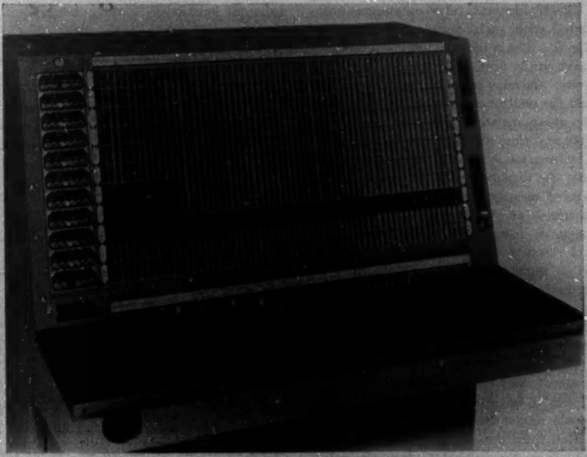

Fig. 6. Display console

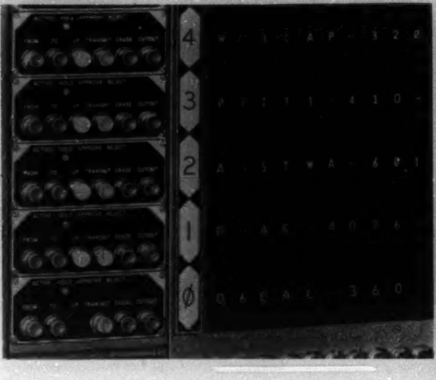

Fig. 7. Close-up view of console

Fig. 8. Display equipment racks

3. By operation of a single button, all data can be concentrated in the lower rows of the display console without changing the prevailing sequence.

4. Similarly, by operation of only one button, a selected row can be cleared of information by transferring the data upward.

5. Characters displayed in a row of indicators can be altered individually or in groups.

6. Data appearing in a row can be composed automatically into a message and transmitted at any speed up to 1,000 words per minute.

7. Individual rows can be removed from service.

Electronic and relay equipment associated with each console are shown in Fig. 8. The apparatus mounted on these racks can be divided into three functional units: the relay register, the shift register, and the control circuits. The purpose of the relay register is to store one flight plan at a time so that it can be processed. The function of the shift register is to enable the display system to transmit and receive messages at any speed and it is designed to be compatible with the magnetic-drum equipment. The control circuits sequence the display, the relay register, and the shift register through their various functions, check for proper operation, detect errors, and malfunctions, and provide alarms to the maintainer or operator.

Fig. 9 is another block diagram of the system equipment with the displays shown in greater detail. Data which appear on the console board can be transmitted from the display by first moving data from the indicators into the relay register, transferring to an electronic shift register, and feeding the information into the transmission line where it will be automatically switched to the proper destination. Incoming messages intended for the display equipment are first received by the electronic shift register as teletypewriter characters, transferred to the relay register, and then to indicators in the display.

The display equipment is designed to handle any communication speed up to 1,000 words per minute. The normal speed will be 1,000 words per minute when communicating with a local drum or another display and 75 words per minute when the message is destined for a distant location.

Automatic Operation of the Display

In normal operation, the display boards are in readiness to receive incoming messages. Such messages, when received, are sensed for a "kind" character which occurs in the preamble of the message. This kind character serves to identify the purpose of the message and initiates an internal program control. The program control can cause one or more of the following actions to be performed:

1. The message may be displayed in an empty row.

2. The rows may be searched to find a displayed flight number which is identical to that contained in the incoming message. The message may then be read into the proper row.

3. Colored lamps may be lighted or flashed to indicate approval or rejection of flight clearances.

4. A reply message may be automatically composed and transmitted.

5. A cancel message may automatically erase information displayed in a particular row; this would normally be the result of action initiated by the operator himself.

Numerous other automatic operations can be performed by the equipment, both in transmission and reception of information, to provide error checking and to prevent loss of information by improper button operation. By combining push-button operation and automatic program operation, the display boards have been designed to perform automatically many functions which air traffic controllers are now handling manually, thus permitting the controller to devote more time to important decisions which should improve the efficiency and safety of air traffic.

Summary

The density of air traffic has increased to the point that the present traffic control system finds it difficult to handle peak loads without causing some delays in schedules. The air traffic controller is required to make numerous manual operations and to scan visually a large amount of air traffic data in performing his duties. An automatic system is being developed wherein all air traffic information, by being reduced to electrically coded form, can be handled by equipment such as automatic switching centers, magnetic-drum storage and processing, and automatic display boards. A testing program is under way at Indianapolis where both simulated and actual traffic will be handled by present-day means and by new systems. It is likely that the best system of air traffic control will combine new operational procedures with new tools such as improved radar coverage and automatic information handling equipment.

Some Properties of Magnetic Fluids

J. E. COOLIDGE, JR.
ASSOCIATE MEMBER AIEE

R. W. HALBERG
NONMEMBER AIEE

SINCE the original announcements of J. Rabinow's investigations of magnetic fluid clutches in 1948,[1] much energy has been expended to make practical use of this phenomenon. Application to computors, machine tools, dynamometers, and automotive clutches are but a few of the areas which have been studied. The results of these application studies have not been as rewarding as originally anticipated, although at least two manufacturers are making a commercial product.

Several years ago, the Borg-Warner Central Research Laboratory initiated a program of insurance research on magnetic fluid clutches. The work has proceeded along two paths: the measurement of the properties of magnetic fluids; and observation of the characteristics of running clutches. This paper is a report of some of the results of the first study.

Basic Principles

A magnetic fluid clutch takes advantage of the solidification of iron powder and lubricant mixtures when exposed to a magnetic field. This control of the state of the fluid allows variation of the force transfer between the elements confining the fluid and, thus, a variable capacity clutch. Theoretically, the form of the clutch elements is only limited by the means to obtain proper magnetic excitation, but operating characteristics provide further limitations.

Objectives of the Program

The initial aim of the magnetic fluid study was to find the relation of material type, particle density, particle shape, fluid properties, flux density, and gap thickness to the shear-stress or force-transfer capacity of the magnetic fluid. Although the study has left many questions unanswered and avenues unexplored, the partial results are presented in the hope they might stimulate additional work and, thus, provide a better understanding of this phenomenon.

Equipment

All shear-stress measurements were carried out on the apparatus shown in Fig. 1. This fixture consists of a U-shaped electromagnet with round pole faces of 0.44 square inch in area, the centers of which are 1.16 inches from the center of rotation, as shown schematically in Fig. 2. The magnet is mounted on a freely rotatable center shaft with spacers between a shaft collar and the magnet to provide an adjustment in gap between the pole faces and the base from zero to 0.030 inch in 0.002-inch intervals and, in larger intervals, of 0.030-inch up to a 0.060-inch gap.

Directly below and parallel to the magnet pole faces, poles of slightly greater area are machined in the steel base plate. The base poles are encircled by calibrated brass rings which are threaded to enable adjustment of the depth from the surface of the ring to the base pole surface. The purpose of the retaining rings is to insure that a constant mixture concentration is exposed to the uniform magnetic field of the pole pieces. This construction necessarily restricted the movement of the magnet and made measurement of the shear stress difficult. However, after much experimenting, a satisfactory technique was developed.

Flux density measurements were made by a 25-turn search coil and a ballistic galvanometer. The search coil is wound as close to the end of the magnet pole face

as possible. The shear-stress characteristics of the fluids were obtained by means of torque measurements, using the spring scale and associated gear. The complete setup is shown in Fig. 3. Because of the restricted movement of the magnet, the initial yield stress was used as a comparative stress criterion rather than the maximum or ultimate stress. The yield stress of a mixture can be thought of as the transition point between its action as an elastic body and that of a viscous fluid. The yield stress was determined in the following manner. With zero magnet current, a load was set by holding the magnet in position by hand and the spring tension was adjusted. The electromagnet was then energized and the hand released. The maximum load which produced no movement of the magnet following the hand release have the yield stress.

Test Procedure

After the height of the brass ring had been adjusted to the desired gap and the corresponding spacers put on the magnet shaft, the material to be studied was placed on each base pole. It was leveled by means of a razor blade. The unit was then assembled and torque readings taken at various magnet excitations. A variation of less than 4 per cent was observed for any set of observations.

Results

Extensive observations were made on 14 materials; six Carbonyl and eight hydrogen-reduced irons at flux densities up to 9,000 gauss, working gaps of 0.004 to 0.060 inch, and iron-to-oil mixture ratios of 4 to 1, 6 to 1, and 8 to 1. Although dry mixes could not be studied, some measurements were taken with sus-

Discussion

Flux Density

The variation of shear stress with flux density observed in these tests was not as expected. Although other investigators[2,3] have reported a relation B^n, n ranging from 1.6 to 2, a linear relation was most predominant in these measurements. Subsequent tests on running clutches have shown that this difference is probably caused by additional mechanical packing of the magnetic mixture in plate-type clutches. Brede[4] found a linear relation in his drum-type adaption for dynamometer use.

Iron-Oil Mixture and Iron

The results show that the iron-oil ratio and individual irons are both important in determining the shear-stress capacity of the mixture. Actually, the iron-oil ratio is a density effect, as shown by representative irons in Fig. 11. Two significant differences can be observed in this graph: the rate of change of stress with mixture density over this density range among irons of the same type are equal; and the shear-stress capacity of normal carbonyl irons increases much more rapidly than that of hydrogen-reduced irons.

The relation of particle size and shape to these differences is not clear. There definitely appears to be no relation between average particle size and the stress level among the same type over the range 3 to 40 microns. There is some evidence, however, that particle shape has an influence on the slope of the stress-density relation. The characteristics of an irregularly shaped carbonyl iron and an electrolytic iron were found to be similar to the hydrogen reduced irons, as shown in Fig. 11.

The low density IRN-8 and IRN-9 irons failed to indicate any shear-stress capacity at the maximum flux excitation. Extremely low capacities were also observed on a low-density flakey sponge iron and a flakey stainless steel, although the average particle size was much greater.

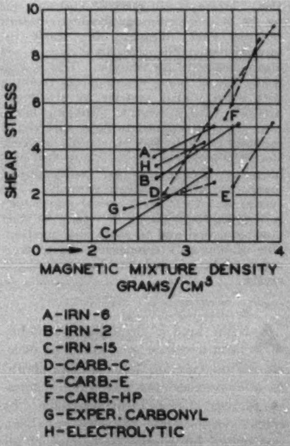

Fig. 11. Shear stress versus magnetic density for several iron powders

GAP THICKNESS

The unusual variation of shear stress with working gap, shown in Figs. 8 and 9, is puzzling. When first observed, it was felt that the structure was something peculiar to the test apparatus but the variation among powders and reproducibility of the measurements dispelled this theory. The Carbonyl irons showed little variation between 0.006 to 0.060 inch with a slight maximum occurring between 0.010- and 0.020-inch gap.

The hydrogen-reduced iron showed a much greater and more erratic variation than the Carbonyls, as high as a 50-per-cent change in stress accompanying a 0.004-inch change in working gap. The significance of these variations is not known.

SUSPENSOID

In all the measurements discussed so far, a light transmission oil was used as a suspensoid. Some observations were made using Aroclor, *DC-200* (silicone), and Hevyteck 95, and little variation in shear-stress capacity was noted. Subsequent measurements in running clutches showed that this independence extended to even dry mixes. Then results concur with those of a previous investigation.[5]

Conclusions

It is believed that the following conclusions can be drawn from this investigation:

1. There is a great difference in the shear-stress capacities of iron-powder fluid mixtures, with particle density being an influential factor. Some of the minor variations may be masked in an actual clutch installation because of mechanical packing and mixture concentration, but the over-all variation is significant.
2. The shear-stress capacity of a magnetic fluid is proportional to the flux density.
3. The shear-stress capacity is independent of the fluid mixed with the iron powder.
4. For maximum force transfer, spherical-shaped iron powders are best. There is probably some significance to the particle size distribution, but it is not conclusive in these measurements.
5. No explanation is evident for the variation in shear-stress capacity among irons of the same type.

An Electronic System for Air Traffic Control Information

R. M. KALB
MEMBER AIEE

Synopsis: A digital information processing system has been built for handling and storing flight plans and weather information. Messages are received and sent out by the system automatically over standard teletype lines. Requests for stored information and directions to change it are also transmitted by teletype. This system is capable of being connected in common with other similar systems by a teletype network with automatic switching facilities. It was designed to form part of the common system for air traffic control. Received messages are randomly filed in a magnetic drum store and subsequently found by means of their contents. The system has a complete logical plan which is designed to give a specific result for each possible action and to cause any questionable or obviously erroneous received messages to be printed out for supervisory review.

A NEW kind of electronic system has been developed as part of an over-all, nation-wide air-traffic control plan[1,2] to accommodate the increasingly pressing problem of dispatching air traffic. In recent years, this problem has been aggravated by a growing volume of all sorts of traffic to be monitored—military, private, and commercial—and planes operating at higher speeds have reduced the time available for action. The terminal control problem is complicated by greater landing speeds and by the widening range of speeds of approaching aircraft. At one end of the speed range are found helicopters, at the other end jet airplanes. The trend to all-weather flying imposes a severe terminal problem when planes are landing and taking off under poor weather conditions. The problem of handling today's air traffic, and that of tomorrow, is being resolved under the planning of a common system for air traffic control.[3,4] The common system includes navigational aids, airborne equipment, and ground-based electronic aids for the men who control the air traffic—the controllers. The subject equipment of this paper, a flight plan storage and processing equipment, provides, as part of these ground-based aids, a high-speed, unindexed, electronic filing system.

Control of Air Traffic

Controllers who monitor the cross-country air traffic are located in Air Route Traffic Control (ARTC) centers, about 25 in number. These communicate with airplane pilots and dispatchers through about 500 stations. Three-fourths of these stations handle communications only, the other fourth are control towers at important airports. The geographical area handled by one ARTC center varies greatly according to the density of surrounding air traffic and may contain anywhere from two to seven control towers. The controllers stationed in control towers are concerned only with immediate departures and arrivals of planes at their airport. In handling a flight from take-off to touchdown, both kinds of controllers take action but those at the ARTC centers exercise the continuing monitoring control.

The electronic system makes information on all pertinent flights quickly available to a controller when the time for his action approaches, and otherwise on demand. It receives and delivers weather reports automatically and keeps a file of the flight plans for all air traffic within an area. Table I lists the contents of these types of messages. Routine processing of the information is

done automatically. Facilities are provided for altering the filed information and for keeping it up to date. A permanent record is made of all the information handled in the system.

FLIGHT PLANS

Air-traffic information filed is in the form of flight plans. A flight plan is an itinerary of an aircraft plus pertinent data about the craft. Airways, like highways, are designated by route codes. An airway code is a color and a number, e.g., *green 14* or *red 9*. Thus, it is possible to construct an itinerary by a sequence of codes and reporting points, or "fixes," with the altitude of each portion of the route also given. Such a plan is originated by the pilot or by a dispatcher and may be presented via teletype message, voice, radio, or on a written form. The information is reduced to a standard format and put on teletype lines for introduction into the system. A flight plan received in teletype code can enter the electronic system directly; received in any other form it is relayed through an operator who prepares the proper teletype message.

Each flight plan message comprises the following portions:

1. Teletype address signals for automatic line switching and machine clearing (6 characters).
2. A preamble consisting of the address from which the message is sent and codes for the kind and length of message (6 characters).
3. A criterion of message selection consisting of the departure time and airport, and the aircraft identity number (18 characters).
4. General information including arrival time and airport and an alternate arrival airport, plane type, instrument equipment, speed, fuel, and priority, and any restrictions applicable to the flight (35 characters).
5. Route information consisting of airway, altitude, fix and time (1 to 9 sets of 17 characters each).
6. Sign-off, figures shift-carriage return-letters shift, to denote the end of the message (3 characters).

Messages handled by the system are tabulated in Table II. They include both flight plans and intructions concerning the disposition of flight plans. Incoming flight plans to be filed constitute one type of message. Flight plans which modify an already existing one are messages of a second type. Instructions may be to read out a particular flight plan or to cancel one or to activate one whose departure time is imminent; these three kinds of instructions form three more types of message. The system includes provision for storing weather reports as well as flight plans, and the filing, reading out, and cancelling of such reports necessitate three more message types. A reply or an alarm message is generated in each case to complete a cycle of action by the system.

Nature of the Automatic Operations

In processing a received message of any type, the system attempts a sequence of four logical steps. These steps, with their logical alternatives, are diagrammed for the filing process in Fig. 1. The first step is to verify the format of the message in certain respects to make sure that the message is properly composed for the system. The next step is to search the file of stored information. This search is made according to the nature of the incoming message, either to guard against accepting a duplicate message or to find a stored message which is to be modified or cancelled. The third logical step is disposal of the message. This step may be to store the message or to read out, modify, or cancel one already stored. Details of this step are given in Fig. 2. The final step is to prepare a reply giving external indication that the action initiated has been completed or that it cannot be.

Failure of the system to comply or its inability to proceed with any logical step initiates an alarm message. If the format of the incoming message fails verification, the message as received is printed

Table I. Contents of Messages Filed

Characters	Flight Plans		Weather Reports
6	signals for teletype line switching and machine clearing		same
6	preamble:	address	same
		kind of message	
		length of message	
18	criterion:	departure time	time of observation
		departure airport	place of observation
		aircraft identity	the word "weather"
35	general information:	arrival time	text of report
		arrival airport	
		alternate arrival airport	
		type of aircraft	
		speed of aircraft	
		fuel, hours	
		instrument equipment	
		priority of flight	
		restrictions on course	
17 (1 to 9 sets)	route information:	airway	
		altitude	
		fix and time	
3	sign off:	figures shift	same
		carriage return	
		letters shift

out to a supervisor at the machine center who then handles the situation by the exercise of his own judgment. All other alarms result in the composition of a message containing only a preamble and criterion. If a flight plan received for filing has the same aircraft identity number and departure airport as a plan already stored, that plan is rejected and the preamble and criterion of the plan in file are transmitted to the sender who thereby is advised of the conflicting plan; he then can take further action by cancelling this plan before filing the new one or by having all of the filed plan read out to him as the basis for deciding further action.

As soon as a message is filed initially, the complete text of the message is read back from storage and transmitted to the sender. This gives him at once a verification and a typed copy of the flight plan he has on file. When any message in file is cancelled, it thereupon is read out in its entirety to a tape perforator; the record of this perforator, termed legal storage, constitutes a complete listing of all messages upon which action has been completed. Tape from the perforator can later be fed into a page printer to reproduce a typed copy of any desired portion of the record. The system deletes spaces from the received message before storing the information contained in it, and restores the spaces as the message is read out. This action is based on a fixed format for each type of message.

Buffer registers, called incoming message-holding units, receive messages as they arrive and introduce them into the storage system when it is ready after they have been verified. An outgoing message-holding unit similarly accepts the stored information necessary for a reply and relays it to a teletype line as available. Incoming and outgoing message-holding units operate in pairs; an incoming unit will accept a message but will not process it into the system until the incoming unit has acquired a complementary outgoing message-holding unit to receive the reply. The preamble of the incoming message is transferred directly to the outgoing message-holding unit for utilization by it in formulating the reply message.

A high-speed message-holding unit is provided also. This is a dual unit which handles information both ways between the storage system and a display panel console at speeds one order of magnitude greater than in the teletype lines.

A special feature of the system is a clock-actuated read out. By action of this device, the storage is searched completely every 10 minutes and all plans for flights due to depart within the succeeding 20 minutes are selected automatically and transmitted to the airport of departure. When a flight plan is so activated, a status-indexing character filed with it by the system is changed to indicate "enroute status." This indication prevents the same flight plan from being read out automatically again during a subsequent periodic review. Provision is made also for filing plans with an enroute status initially. This is done when the plan is filed within 10 minutes of its departure time or when the controller modifies a plan already under his scrutiny.

Properties of the Equipment

Pertinent numerical characteristics of the equipment are given in Table III.

Courtesy Civil Aeronautics Administration, Technical Development and Evaluation Center

Fig. 3. Flight plan storage and processing equipment

The filing system utilizes magnetic drum storage with a capacity of 2,000 flight plans and weather reports. These are grouped into two categories, short and long. A short message consists of not more than 115 characters, a long message can be twice as long. Information is stored in the teletype code with the characters serial and their five bits in parallel. The total information storage capacity of the drum is 316,250 characters or 1,581,250 bits.

Stored information is so arranged that during the search only the criterion portion of each message is scanned. With this arrangement, the entire contents of the information store can be searched in eight drum evolutions, approximately two-fifths of a second.

The timing pulse rate of the drum is 114 kc. Using a fivefold interlace, information is read and written at about 23 kc. Conversion between the teletype line speed of 460 characters per minute and internal system speeds of 23,000 characters per second is accomplished through the incoming and outgoing message holding units. More details of the equipment are published elsewhere.[5]

A complete set of the equipment which forms the system described has been installed for evaluation at the Technical Development and Evaluation Center of the Civil Aeronautics Administration at Indianapolis, Indiana. An over-all view of the installation is shown in Fig. 3. This installation is being connected to operate through an automatic teletype switching center,[6] a modified *81D1* system, and in co-operation with data transfer and display equipment described in a companion paper.[7]

Future Plans

Planning for the air-traffic control system calls for dividing the country into control zones, perhaps 10 or 15 altogether, and centralizing the control for each zone in one similar equipment located within it.[8] When this is done, equipments for adjacent zones would be connected by teletype lines with automatic switching so that two equipments could "converse" with each other to establish flight plans for interzone traffic. The system logic for such operation was examined prior to planning the present system, and it was designed according to principles allowing such interconnection of equipments.

Requirements for the ultimate system will not be known until after the present one is evaluated. One matter to be settled concerns the relative demands for weather and traffic information and whether such information should be filed on one equipment, as in the present instance, or on separate equipments.

Another question to be determined is the possible need for adding a time-reservation facility to the system.[9] The purpose of this facility would be to limit the number of landings and take-offs scheduled during periods of 1 hour or less for each airport. The limit would, of course, have to be variable because of the influence of weather and other conditions which affect the acceptance rate of an airport. The means for including time reservations in the air-traffic control system were worked out during the early planning of the present equipment, and it was so planned as to permit the addition of the time reservation feature to subsequent models.

The system described constitutes an initial venture into automatic teletype filing and processing of alphabetical and numerical information. It is also the first serious attempt to mechanize the routine of handling air-traffic control information. With the possibility realized of machines composing messages and conversing via teletype lines, facilities are at hand to further the advance of clerical procedures by means of electronics.

Machine Testing for Deviation of Data from a Poisson Distribution

F. A. HADDEN
ASSOCIATE MEMBER AIEE

THERE are many situations in which data are obtained describing events that occur at random. If the mechanism causing the random events is such that the events are independent and the probability of occurrence in any given interval of time is constant, the occurrence is described by the Poisson distribution. In a population of events which are normally expected to occur according to the Poisson distribution, certain events may occur as the result of special factors which operate in relation to them only. In such cases, these specially influenced events will not fall within the Poisson distribution that describes the rest of the population. It may be desirable to study the factors causing their peculiar occurrence and this will require that the normally occurring events be separated from the normally occurring ones. A practical machine method for making this kind of separation for any data which are Poisson-distributed is outlined. For clarity, the techniques will be described in terms of a particular example but other applications are of course possible.

A type of event which is usually Poisson-distributed is the in-flight failure of vacuum tubes in a piece of air-borne electronic equipment. The data in this case could be the number of failures of each tube type in the same time period, as

* Tested out of range at this point.

shown in Table I. These data will be used as the example throughout the paper. The purpose of the testing described is to check the circuit application and tube design criteria for each tube type to make sure that the tubes are neither overloaded nor underloaded relative to the other types in the equipment. The problem is to identify the tube types having failure probabilities significantly different from those for the average tube type.

Since failures occur at random, it is expected that there will be a variation in the number of failures of each tube type. The average type will occasionally have a number of failures which is either unusually high or unusually low, while the abnormal type will generally have an unusual number of failures because of design or other differences. The separation test must be able to distinguish between the average and abnormal types without too many mistakes. The test described is based on determining from the mean of the data at hand the range of numbers of failures that will include the average tube types a reasonable fraction of the time.

For the Poisson distribution, there is no simple equation relating the mean number of failures m of the average tube types and the upper limit of the range H and lower limit of the range L; but the relation can be plotted as a graph or can be approximated by simple equations. From Poisson tables, such as those by Molina,[1] the total (cumulative) probability of there being H or more failures for any given mean m can be obtained as well as the total (cumulative) probability of there being L or fewer failures for any given mean m. For use in testing, the approximate relations between H and m and L and m for various fixed values of probability are needed. Experience has shown that for identifying a category, e.g., a tube type not belonging to the common Poisson distribution it is reasonable to use two probability values such as 1/100 and 1/1000. These two probabilities define the four curves: very low (VL), low (L), high (H), and very high (VH). All four curves are a function of m alone.

For many applications of the technique presented here, such as the work on equipment failures[2] which prompted this paper, a category which has only one occurrence, however improbable, does not warrant investigation except in very special cases which can be treated separately. The curves and equations given here have been adjusted so that two is the lowest number of occurrences which will test as greater than H.

Since the Poisson and Gaussian distributions approach each other for large values of the mean, a Gaussian distribution with the same mean, standard deviation, and cumulative probabilities as the Poisson is an appropriate basis for approximation. A good fit was obtained to each of the desired curves relating the range limits to the mean for use with the machine procedures outlined in the following. The four equations which are satisfactory, for all positive values of m are

$$VL=m-3.09\sqrt{m}+1.2$$

$$L=m-2.33\sqrt{m}+K$$

$$H=m+2.33\sqrt{m}+1.1$$

$$VH=m+3.09\sqrt{m}+1.6$$

In Fig. 1, the actual Poisson points for the probabilities 1/100 and 1/1,000 are the dots in circles and squares respectively. The approximation equations given in the foregoing are the plotted curves; there are two curves for L, one with $K=0.3$ and one with $K=0$. The $K=0.3$ approximation is a very close fit to the 0.01 (or 1/100) probability all the way, while the $K=0$ approximation deviates a little for low m and L; e.g., the probability is about 0.007 for $L=3$ and 0.004 for $L=0$. The choice of a value for K is discussed in the following. The constraint of never accepting an H less than two is convenient for this approximation in the middle range of m, but it does raise H slightly for the lower range of m. The square root required in the equations may be avoided by using the ratio of two polynomials in m as an approximation, but this is limited to a restricted range of values for m.

These equations give the limits within which the number of failures of an average tube type will almost always fall, based on the expected mean number of failures for the tube type. If all tube types appear in the same number of sockets, then the expected mean and the range limits will be the same for all the tube types; but if the number of sockets varies with the tube type, then the expected means will be proportional to the number of sockets, with the range limits varying correspondingly.

In the example given in Table II, there are 15 tube types in 110 sockets with a total of 1,529 failures. The failure rate per socket is

$$\frac{1{,}529}{110}=13.9$$

or the expected mean is the per-socket rate times the number of sockets that the tube appears in, e.g., $13.9\times5=69.5$ for the *2D21* tube and $13.9\times1=13.9$ for the *2J56* tube, etc.

For each tube type, the range limits are found from the equations or the curves. It is seen that the *6J6*, which has the largest number of failures, is actually within limits whereas the *2J56* with a moderate number of failures is above the *VH*-range limit.

Caution must always be used in the testing of categories which have had unequal exposure to the mechanism causing the occurrences. In the example, the unequal exposure was caused by the variation in the number of sockets using each type of tube. In another kind of analysis, it might be caused by one piece of equipment operating more hours than another. In general, however, the basic rate from which the expected mean for each category is determined is the number of occurrences per unit of equipment per unit of exposure.

If the data include failures from abnormal tube types as well as from the average type, the value of the mean calculated from all the data can be shifted by the failures of the abnormal types. One extremely high failing type can mask a few moderately high failing types and even force a few average types which happen by chance to be a little low to appear abnormally low. In the example, the *4C35* was masked by the *2J56* and the *6Y6* until the data were adjusted. The amount of care required to protect against these effects will depend upon the character of the data. The detailed procedures described here are for the simple case with few abnormal types and small penalty for minor errors. More complicated data can be handled by a relatively simple extension of the adjustment techniques.

Machine Procedure Outline

For the procedure to be outlined it is assumed that each category, e.g., tube type, to be compared is represented by one accounting machine card such as those used in International Business Machines. These cards are referred to as category cards. Each category card has punched in it the number of occurrences, e.g., failures, and the exposure, e.g., number of sockets, for that category in appropriate units. In addition to the category cards there are two summary cards. One of these, called the first summary card, has the total number of occurrences for all categories and the total exposure for all categories punched in it. The first summary card is placed in front of the category cards and the blank second summary card is placed behind. The cards are passed in this order through a calculating punch:

From the first summary card, store and retain for further use the total number of occurrences for all categories and the total exposure for all categories. Calculate the mean rate of occurrence per category per unit exposure and store this quantity for further use. As each category card passes, multiply the exposure for that category by the mean rate of occurrence to obtain the expected mean number of occurrences for that category. Using the equations given, calculate L and H, test the number of occurrences for that category to see if the number falls outside the 1/100 range and then, if the category does not test outside, pass to the next category card. In calculating L, the constant $K=0.3$ should be used unless insufficient capacity is available in the calculating punch to make the number of occurrences test as outside the range on the L end for m less than 1.

If the category does test outside, calculate the appropriate *VH* or *VL* and test to see if the number of occurrences falls outside the 1/1000 range. In any case, subtract the number of occurrences for that category from the total number of occurrences stored and subtract the exposure for that category from the total exposure stored. The purpose of these subtractions is to eliminate those categories that are known to differ from the average distribution so that in subsequent iterations they will not affect the mean rate which describes the average categories. Punch the card to describe the way it falls outside the ranges and pass to the next category card.

Punch the adjusted total number of occurrences and total exposure into the second summary card which follows all of the category cards. Other groups of category and summary cards can follow and be tested automatically without any change in the machine. After all groups being tested have made the first pass, they are ready for the first iteration. Replace the first summary card by the second summary card and replace the old second summary card by a new second summary card. Repeat the preceding steps but ignore the already marked cards.

The procedure is repeated as many times as necessary but some experience has shown that even one iteration may be sufficient for many applications. More complicated data can be handled by eliminating only *VH* and *VL* categories on the first pass or by eliminating only the one most extreme *VH* or *VL* category each pass until all the *VH* and *VL* categories are gone. It is not necessary to rearrange and add summary cards physically as just described because the same effect can be achieved by properly locating extra blank cards to be used as the new second summary cards when the old ones are advanced to first summary cards. The replacement of a first by a second summary card only requires that the cards be turned over and passed through the machine in the reverse order, using a different machine control board which takes this into account.

A Tapered Strip Transmission Line for Pulse Transformer Service

F. G. PRIMOZICH
ASSOCIATE MEMBER AIEE

E. R. SCHATZ
ASSOCIATE MEMBER AIEE

J. B. WOODFORD
ASSOCIATE MEMBER AIEE

THE need for wide-band impedance-transforming devices has long been recognized. The increasing interest in the use of very short pulses of millimicrosecond duration in radar, communication, and other systems accentuates the demand for a device which is capable of faithfully transforming such pulses. As the bandwidth and upper cutoff frequency increase, it becomes more and more difficult to construct suitable lumped-parameter or iron-core transformers of conventional design. Thus, the trend in recent years has been toward distributed systems, particularly of the tapered transmission line variety. Various tapers such as the linear,[1] Bessel,[2,3] exponential,[4-8] and hyperbolic[9] have been proposed and analyzed by several investigators. In addition, many different physical structures employing these tapers have been constructed and tested experimentally. These were the 2-wire open line,[4,5] the concentric circular cylinders,[7-9] and the shielded wire and tape helices.[10,11] By and large, each experimental model has been physically bulky and difficult to construct. It is the purpose of this paper to investigate a tapered transmission line design which is reduced in physical bulk and which can be fabricated more economically.

The Rectangular Strip Transmission Line

A structure which can readily be applied to the design of a tapered transmission line is the rectangular strip line. A rectangular strip transmission line consists of a thin conducting strip of width $2a$ which is suspended coaxially by insulating material of permeability μ_1 and permittivity ϵ_1 in a conducting right rectangular cylinder of width $2c$ and height $2b$, which serves as the outside sheath. The cross section of this line is shown in Fig. 1.

The rectangular strip line can be either completely enclosed, as shown in Fig. 1, or the perpendicular sides can be eliminated, as shown in Fig. 2. These two lines are essentially identical in their electrical characteristics over a wide range of ratios of the dimensions. In this treatment, the rectangular strip line without sides, Fig. 2, will be used exclusively. However, all conclusions can also be applied directly to the line with sides.

It has been shown by other authors[10] that a tapered transmission line can be designed by assuming that the characteristic impedance at a point can be determined from the equations derived for a uniform line. This is a valid assumption, provided the taper is not very rapid.

As shown in the Appendix, the phase velocity of a uniform rectangular strip line is equal to $1/\sqrt{\mu_1\epsilon_1}$ and the characteristic impedance is

$$Z_0=\sqrt{\frac{\mu_1}{\epsilon_1}}\,\frac{1}{4}\,\frac{K}{K'} \tag{1}$$

where K and K' are complete elliptic integrals of modulus k. Equations for finding k are given in the Appendix.

By use of these equations and the tables,[12,13] families of curves of normalized characteristic impedance $Z_0\sqrt{k_r/\mu_r}$ versus the dimensional ratio a/c are plotted for various values of the ratio b/c. The resulting curves are shown in Fig. 3. Here $k_r=\epsilon_1/\epsilon_0$ and $\mu_r=\mu_1/\mu_0$, where ϵ_0 and μ_0 are the values for free space.

With an air dielectric the range of impedance levels readily obtainable is 20 to 300 ohms. It should be noted, however, that any magnitude of impedance is theoretically possible since the curves approach the ordinate asymtotically. The only practical limitation is the ability to control accurately the dimensions of the inner strip as the ratio a/c approaches zero. The impedance curves can be raised or lowered by proper choice of ϵ_1 and μ_1.

Design of an Exponential Strip Line

The steady-state and transient characteristics of the exponential transmission line have been widely discussed.[4,5,7,8,10] Schatz and Williams[8] have determined the pulse response of the exponential line and have established the criteria for the design of such lines as pulse transformers, i.e., length and flare requirements for the transformation of a particular pulse of known shape and duration have been given. This study will concern itself mainly with the design of a rectangular strip line with exponential taper although, with the curves given in Fig. 3, any form of taper could be considered.

In an exponential line the characteristic impedance at a point varies as an exponential function of the distance from the sending end

$$Z_x=Z_0\epsilon^{\gamma x} \tag{2}$$

where

γ = flare coefficient which is assumed positive
x = distance from the sending end of line
Z_0 = characteristic impedance at the sending end of line

After the length and flare requirements have been established for a particular pulse application, it is only necessary to taper the center conductor (the strip) of a rectangular strip line in such a way that the characteristic impedance along the line will follow that given in equation 2. From equation 2 the impedance at a given position x on the line is known. For given values of b and c, the value of a necessary to give the required value of

Primozich also wishes to acknowledge the support of the Buhl Foundation through a Buhl Fellowship.

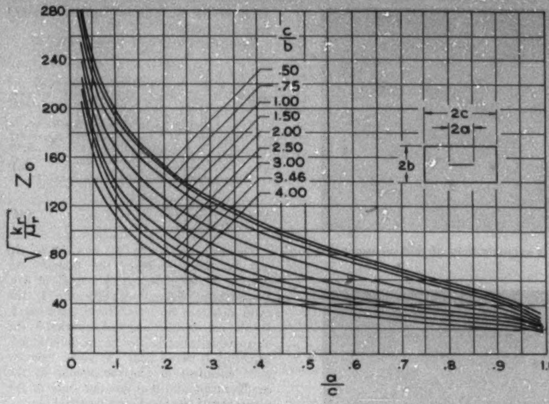

Fig. 3. Normalized characteristic impedance of the rectangular strip line in ohms

impedance at the point x can be determined from Fig. 3; i.e., a as a function of x, distance along the line, is now known and the inner conductor is then tapered accordingly. The dimensions at the sending end of the line are, of course, functions of desired impedance level, of space limitations, and of breakdown and power-handling requirements.

One of the particular space-saving possibilities of the tapered rectangular strip line is that it can be conveniently rolled up; see Fig. 4. This particular model was designed to be 10 meters long with an impedance transformation of 4. The impedance level at the low end is 25 ohms and at the high end 100 ohms. The total dimensions of the line shown in Fig. 4 are about 2 by 4 feet. For convenience, in rolling, this line was constructed without sides, but it would be a simple matter to add sides in any commercial fabrication.

Pulse Response of the Strip Line

An experimental determination of the pulse response of the line in Fig. 4 was made. The line was terminated with an impedance equal to the impedance level at the output. The input pulse is shown in Fig. 5 and the output pulse in Fig. 6. The length of pulse at the input is about 36 millimicroseconds. The output pulse is to the same scale.

Conclusions

It can be stated that the rectangular strip line is particularly suited to tapered transmission line design. Because of the flat shape it can be conveniently rolled or placed against a flat supporting surface; therefore, such a line is definitely a space saving device. In addition, because of the simple construction, tapering of the inner conductor is easy. Printed circuit techniques might also be used in the manufacture of such a line, greatly reducing the complexity of fabrication. All in all, this type of line is a space-saving, cost-reducing device which can help make the use of tapered transmission lines more practical.

Appendix. Phase Velocity and Characteristic Impedance

If the cross section shown in Fig. 1 is transformed conformally into a section of an infinite parallel plate transmission line, the characteristic impedance and phase velocity can be determined. The capacitance and inductance per unit length as well as the characteristic impedance and phase velocity of a parallel plate line are well known.[13] A section of the parallel plate line is shown in Fig. 7.

$$c/l=\epsilon_1\frac{d}{e}=\text{capacitance per unit length} \qquad (3)$$

$$L/l=\mu_1\frac{e}{d}=\text{inductance per unit length} \qquad (4)$$

$$Z_0=\sqrt{\frac{\mu_1}{\epsilon_1}}\,\frac{e}{d}=\text{characteristic impedance} \qquad (5)$$

$$v=\frac{1}{\sqrt{\mu_1\epsilon_1}}=\text{phase velocity} \qquad (6)$$

Since the capacitance and inductance are invariant in a conformal transformation, the characteristic impedance and phase velocity determined for the transformed line also apply to the original transmission line. Now the required transformation must be performed. Since the cross section shown in Fig. 1 is symmetrical, the problem may be solved in one quarter of the section; see Fig. 8.

This section can be transformed into one of four identical parallel plate lines that are electrically in parallel. If e is the separation and d is the width of an equivalent parallel strip line, the section in Fig. 8 will transform into the section shown in Fig. 9. The object of the transformation is to obtain the dimensions e and d in terms of a, b and c.

It has been shown[14] that from a Schwartz-Cristoffel transformation which transforms Fig. 8 in the Z plane into Fig. 9 in the W plane the following relationships can be derived

$$\frac{K_0}{K_0'}=\frac{c}{b} \qquad (7)$$

$$\frac{K}{K'}=\frac{4e}{d} \qquad (8)$$

The subscript 0 denotes the Z plane. K and K' are complete elliptic integrals of modulus k, which is given by the following relationship

$$k^2=\frac{[sn^2(k_0,Z_4)-sn^2(k_0,Z_3)][sn^2(k_0,Z_1)-sn^2(k_0,Z_2)]}{[sn^2(k_0,Z_1)-sn^2(k_0,Z_3)][sn^2(k_0,Z_4)-sn^2(k_0,Z_2)]} \qquad (9)$$

where Z_1, Z_2, Z_3, and Z_4 are the co-ordinates of the points, as indicated in Fig. 8.

$sn(k_0, Z)$ is a Jacobian elliptic function with modulus k_0 to which the following definitions apply.[15] Let

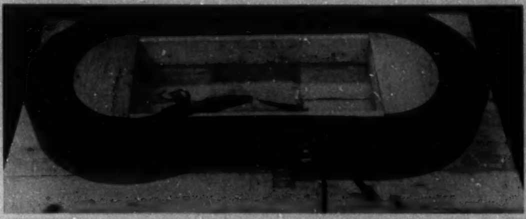

Fig. 4. Rolled-up tapered strip line pulse transformer

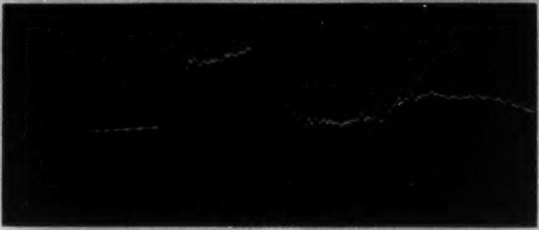

Fig. 5. Input to pulse transformer. Pulse width is approximately 36 millimicroseconds

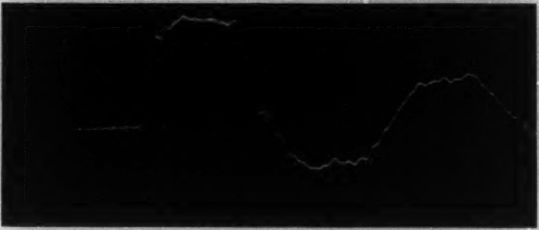

Fig. 6. Output of pulse transformer

$$\mu=\int_0^{\varphi}\frac{d\varphi}{\sqrt{1-k^2\sin^2\varphi}}(k^2<1) \tag{10}$$

$$=\int_0^{q}\frac{dt}{\sqrt{(1-t^2)(1-k^2t^2)}}(t=\sin\varphi) \tag{11}$$

where

$\mu=F(\varphi, k)$ = elliptic integral of the first kind
φ = amplitude
k = modulus

$$\sin\varphi=sn(k,\mu) \tag{12}$$

$$\cos\varphi=cn(k,\mu)=\sqrt{1-sn^2(k,\mu)} \tag{13}$$

$$dn(k,\mu)=\sqrt{1-k^2sn^2(k,\mu)} \tag{14}$$

The complementary modulus is

$$k'=\sqrt{1-k^2} \tag{15}$$

$$K=\int_0^{\pi/2}\frac{d\varphi}{\sqrt{1-k^2\sin^2\varphi}}=\text{complete elliptic integral} \tag{16}$$

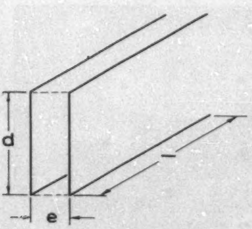

Fig. 7. Parallel plate line

$$K'=\int_0^{\pi/2}\frac{d\varphi}{\sqrt{1-(k')^2\sin^2\varphi}}=\text{complete elliptic integral of the complementary modulus} \tag{17}$$

A complete discussion of the properties of Jacobian elliptic functions appears in references 16 and 17.

The following are some relations which can be used in the evaluation of the functions[18]

$sn(k, 0)=0$ $\qquad sn(k, K)=1$
$cn(k, 0)=1$ $\qquad cn(k, K)=0$
$dn(k, 0)=1$ $\qquad dn(k, K)=k'$

$$\begin{aligned} sn[k, (K+jK')]&=1/k \\ cn[k, (K+jK')]&=jk'/k \\ dn[k, (K+jK')]&=0 \end{aligned} \tag{18}$$

In Fig. 8 it can be seen that if $Z_1=0$, $Z_2=K_0(1-a/c)$, $Z_3=K_0$, and $Z_4=K_0+jK_0'$, then

$$sn(k_0, Z_1)=sn(k_0, 0)=0 \tag{19}$$

$$sn(k_0, Z_3)=sn(k_0, K_0)=1 \tag{20}$$

$$sn(k_0, Z_4)=sn(k_0, K_0+jK_0')=1/k_0 \tag{21}$$

If the ratio $c/b=K_0/K_0'$ is known, a value of the modulus k_0^2 can be obtained from the tables.[12]

Equation 9 can now be simplified to

$$k^2=\frac{\left[\left(\frac{1}{k_0}\right)^2-1\right]\left[-sn^2(k_0, Z_2)\right]}{\left[-1\right]\left[\left(\frac{1}{k_0}\right)^2-sn^2(k_0, Z_2)\right]} \tag{22}$$

$$k^2=\frac{sn^2(k_0, Z_2)(1-k_0^2)}{1-k_0^2sn^2(k_0, Z_2)} \tag{23}$$

$$k^2=\frac{(k_0')^2sn(k_0, Z_2)}{dn(k_0, Z_2)} \tag{24}$$

The values of $sn(k_0, Z_2)$ and $dn(k_0, Z_2)$ can be obtained from the tables[12] for various values of k_0 or c/b and Z_2 or a/c. Once these values are determined, the ratio $4e/d$ can be found from equation 8. By the use of this ratio and equation 5, the characteristic impedance can be determined. Equation 6 shows that the phase velocity is independent of the dimensions of the configuration and is a function only of the constants of the insulating material.

It is of interest to note that the characteristic impedance of a strip line as shown in Fig. 2, but in which the outer conductors extend to infinity, is essentially identical to the characteristic impedance of the enclosed line of Fig. 1 for all values of c/b which are plotted when a/b is less than 0.4 and is also for the entire range of a/b for values of c/b greater than 3. Thus, it might be concluded that the completely enclosed line is essentially identical in this range with the line with the finite-plate outer conductor.

Cold-Cathode Counting Circuits

H. L. FOOTE
ASSOCIATE MEMBER AIEE

IN RECENT years, considerable emphasis has been placed on high-speed counting devices for use in electronic computers and designed to operate at pulse rates of the order of 100 kc, and higher. These of necessity involved hot-cathode electron tubes.

There are, however, certain counting and computing problems to be met which do not require the extreme speeds of the complex computers. Several low-speed (up to 700 pulses per second (pps)) counting devices have been evolved using cold-cathode gas triodes. These tubes have the advantage of requiring no heater power with attendant thermal shock, and of having a life dependent upon the number of on-off operations rather than upon hours of operation. The *RCA-5823* tubes used in all of the counters to be described have a minimum life of approximately 40,000,000 operations. Tubes chosen at random and placed on life test in the Stromberg-Carlson laboratory have not failed even after 250,000,000 operations. The standard heater-type tube has a life of about 2,000 hours, with premium types ranging up to 10,000 hours.

Cold-Cathode Gas Tubes

Although this discussion will be limited to 3-element cold-cathode tubes, it should be noted that 2-element and multielement types are available for special purposes. The three elements, Fig. 1, are the main anode *A*, the cathode *K*, and the starting anode *SA*. A sufficient potential difference between the starting anode and the cathode causes the gas in the tube to ionize and the anode-to-cathode gap to conduct. A tube remains ionized until the potential from anode to cathode is reduced below the sustaining value.

In the *5823*, the starting anode must be raised to a minimum of +75 volts above the cathode potential to fire the tube, first ionizing the starting-anode-to-cathode gap, then transferring the discharge to the main-anode-to-cathode gap. The main-anode potential must be above the sustaining value of the main gap of about +85 volts, but not above the self-ionizing value of about +290 volts. Once the main-anode-to-cathode gap is ionized, the starting anode has no further control over conduction. The tube is extinguished or de-ionized by opening either the main-anode or the cathode circuit.

The speed of response of the tube is dependent upon the ionization time (the time necessary to transfer the starting-gap discharge to the main gap) and the de-ionization time. The former is of the order of 20 microseconds, the latter about 500 microseconds.

In general, the main anode is connected to a positive voltage source, and the cathode is connected to ground through a load resistance. A positive potential (usually a short pulse), sufficient to ionize the starting anode-to-cathode gap is applied to the starting anode. A d-c bias potential somewhat lower than this required voltage may be applied to the starting anode, thus reducing the amplitude of the ionizing pulse required.

Decade Counting

The first of two decimal counting chains to be described is shown in Fig. 2. In this circuit,[1] to limit current drain, each tube in firing extinguishes the preceding tube in the counting chain. This is accomplished by using a common main-anode current-limiting resistance *R*. At the instant a tube fires, current through it is limited only by *R*, with the result that the potential of all anodes drops to about +85 volts. Since the cathode of the preceding tube is held momentarily to about +75 volts by its cathode capacitor, there is no longer sufficient voltage to maintain the main gap ionization, and the tube is extinguished.

Start tube *ST* provides the first tube in the counter *V*1 with an enabling bias derived from the divider in the cathode circuit, until the first pulse to be counted arrives. The start tube is ionized by the application of the anode voltage to the circuit. Its cathode capacitor charges, raising the starting anode bias on *V*1 to a value sufficient to allow the first pulse to fire *V*1. When *V*1 fires, the start tube is extinguished by the process described earlier.

Pulse rates and pulse widths are important in choosing the cathode capacitor values, since the operation of the counter depends on the charge time of this capacitor. The bias potential derived from the preceding tube must not be great enough to fire a tube with no pulse present, and conversely, the pulses must not be of sufficient amplitude to fire a tube without the enabling bias. Chains of

Paper 55-197, recommended by the AIEE Electronics Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted March 26, 1954; made available for printing November 24, 1954.

H. L. Foote is with the Stromberg-Carlson Company, Rochester, N. Y.

The circuits of Figs. 1, 3, and 5 to 7 were the work of Stromberg-Carlson Company engineers R. B. Trousdale, G. R. Paul, and the author. Figs. 2 and 4 are described in reference 1.

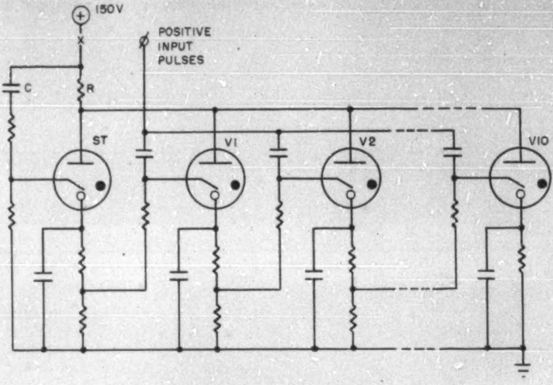

Fig. 2. Cold-cathode decimal counting chain

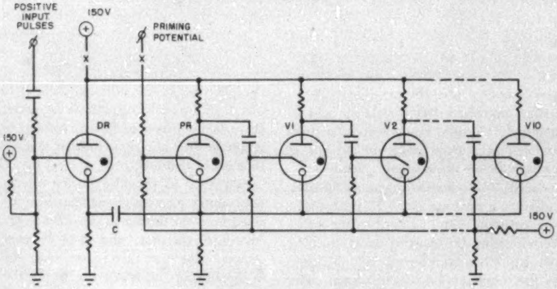

Fig. 3. Cold-cathode decimal counting chain

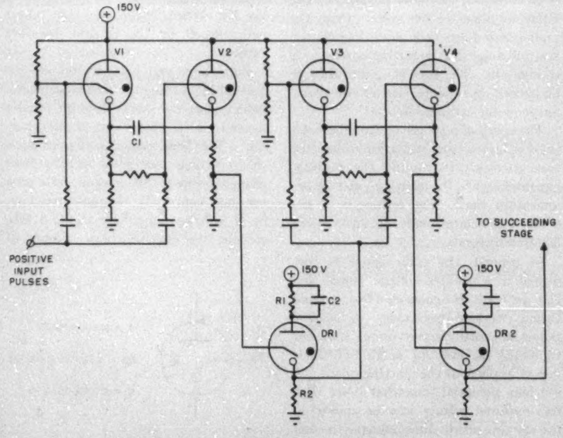

Fig. 4. Cold-cathode binary counting chain

this type have been designed to count at rates up to 200 pps.

A second decade counter, Fig. 3, using a fixed starting-anode bias, employs a common drive tube *DR* so that the pulse source is not loaded by parallel inputs to the counting tubes as in the previously described chain. In this chain also, a start, or prime, tube *PR* is ionized prior to counting. The individual anode and the common cathode resistors are of equal value. Therefore, with a 65-volt drop in the tube, the cathode bus will rise to +42.5 volts. The starting anodes of all of the tubes in the chain are biased to +90 volts. Since the common cathode potential is at +42.5, the starting anode-to-cathode potential is still not great enough to ionize the tube. The starting anode of the drive tube is biased to +50 volts. When a pulse of sufficient magnitude appears on this starting anode, the tube will be ionized raising the cathode potential momentarily +85 volts. At this time, three events occur. The common cathode bus rises to +85 volts as capacitor *C* charges. Since the anode potential of *PR* is +107.5 volts, the tube can no longer maintain ionization and will go out. The drive tube, meanwhile, extinguishes itself by relaxation because of the large cathode resistance. When *PR* goes out, its anode rises sharply from +107.5 volts to +150 volts. This positive pulse appears on the starting anode of *V*1 and adds sufficiently to the fixed bias to fire *V*1. This process is repeated as additional positive pulses are applied to the starting anode of the drive tube.

Pulse repetition rates and pulse widths again determine the value of capacitor *C*. The drive tube must be extinguished with the accompanying common cathode bus potential drop before the succeeding tube can fire. There is, therefore, a time race between the extinguishment of *V*1 and the drive tube and the appearance of the positive pulse on the starting anode of *V*2. Chains of this type have been made to count at pulse rates up to 100 pps.

Binary Counting

For many applications, counting in binary form is preferable to decimal counting because of the savings in tubes that are possible where large numbers are involved. In binary notation a number is described using only two symbols, 0 and 1. Since 2 to the zero power=1, it may readily be seen that any number can be expressed as the sum of powers of two, just as any number in the decimal system can be expressed as the sum of powers of ten. The first ten integers given in the binary scale follow.

In the first binary chain to be considered, Fig. 4,[1] the starting anode of tube *DR*1 receives sufficient voltage to ionize the tube when capacitor *C*1 coupling the cathodes of *V*1 and *V*2 is charged, and *V*1 fires.

Decimal	Binary

4	0100
5	0101
6	0110
7	0111
8	1000
9	1001
10	1010

This occurs on all odd input pulses except the first. Initially, the full supply voltage is applied to the main anode of *DR*1 but, as capacitor *C*2 becomes charged, this voltage decreases. The resistance of *R*1 +*R*2 is great enough to cause *DR*1 to deionize as soon as the starting anode potential falls below the critical point. A sharp pulse appears at the cathode of *DR*1 each time *V*1 fires, and the input to the second counting stage consists of positive pulses at a repetition rate half that of the input to the first stage.

The functioning of the individual stages is as follows: With *V*1 ionized, the starting anode of *V*2 is biased to +50 volts. A positive pulse on the starting anode will then fire *V*2. Capacitor *C*1 is charged to +85 volts because of the ionization of *V*1: as *V*2 fires, the potential at its cathode rises to +85 volts, increasing the potential at the cathode of *V*1 to +170 volts, and *V*1 is extinguished. When *V*1 is ionized again, *V*2 will be extinguished in a similar manner.

This chain is difficult to read directly, and a modification has been designed using two tubes per binary digit, for 0 and 1 representation. In addition, the 0 tubes in each stage must be primed on prior to the start of counting. The chain has been used at pulse rates up to 100 pps.

A simpler type of binary counting chain has been developed which will count at pulse rates up to nearly 700 pps. This circuit is shown in Fig. 5. Here again two tubes per stage are used to indicate 0 and 1, with the 0 tubes primed on prior to counting. The two tubes in stage one are supplied with a fixed bias by divider *R*1-*R*2 so that they can be driven by the input pulses. When *V*2 fires, its cathode potential provides the bias for the second stage. The second pulse ionizes *V*1 and causes *V*2 to be extinguished by the process described for the

first binary chain. When $V1$ is ionized, the cathode potential of $V2$ rises sharply to twice the voltage and then decays rapidly as $C1$ discharges. This sharp rise acts as a pulse to fire $V4$, which in turn extinguishes $V3$. The same process holds for each succeeding stage, the de-ionization of the 1 tube in the preceding stage providing the drive pulse for the succeeding stage. The rate of counting is determined by the time constant of capacitor C and the cathode resistance.

Ring Counters

In the binary system it is necessary to have one 2-tube stage for each power of two required to describe the number. In decimal counting, a decade counter is required for each power of ten required to describe the number, each succeeding decade being driven by a pulse derived from the tenth step in the previous decade. All of the decades but the last must be converted into rings, by returning the output of the last or tenth step to the first step so that it will continue to count around and around as pulses are fed to the input. Fig. 6 shows the way in which this is accomplished for the two decade chains. Circuit operation will be obvious from the preceding discussion.

Binary Decade Counters

There are occasions in computer design where it is desirable to use decimal scaling but to have the count appear in binary form. Since a 4-stage binary counter counts in ring fashion on a scale of 16, it is necessary to account somehow for six extra pulses each decade cycle. The circuit of Fig. 7 shows one method by which this has been done.

The first seven pulses are counted in the normal fashion. When the eighth pulse is received and the 0 tube in the fourth stage is extinguished, its sharp cathode pulse is used to trigger a 2-stage delay circuit, the output of which is phase inverted by transformer $T1$ and coupled to the starting anodes of the tubes in stages 2 and 3. The eighth pulse returns these two stages to the 0 condition, but the derived delayed pulse causes the 1 tubes to be refired, advancing the chain the equivalent of six pulses. Instead of reading binary 8 after the eighth pulse, the chain reads 14 which can be interpreted as 8, since the single symbol 14 never occurs in the scale of 10. Similarly, binary 15 is interpreted as 9, and the binary zero as decimal zero. The stored count is as follows:

Decimal	Binary
1	0001
2	0010
3	0011
4	0100
5	0101
6	0110
7	0111
8	1000, shift to 1110
9	1111
0	0000

The cathode pulse obtained when the 1-tube of stage four is extinguished in going from binary 15 to zero, is used to drive the succeeding binary decade.

While the paper is limited to counting devices, it will be realized that cold-cathode tubes are adaptable to other low-speed computing circuits such as multipliers, pulse generators, delay networks, and memories.

Phenomena Accompanying Transient Low-Voltage Discharges in Liquid Dielectrics

I—Anode Phenomena at Low Currents

ASSOCIATE MEMBER AIEE

ELECTRICAL spark-over between metallic electrodes in a liquid dielectric is followed by a high current-density discharge, the removal of electrode material, the formation of well-defined and characteristic electrode craters and, under some conditions, the production of colloidal suspensions of metal particles in the liquid. The associated phenomena have been the subject of many studies, originally with emphasis on colloidal suspensions,[1,2] and more recently, in connection with "electrical" machining[3,4] processes in which the electrode material removal is adapted for purposes analogous to those encountered in conventional machine tools. Despite the development of an extensive electrical machining art the physical phenomena involved have been incompletely understood. The authors have conducted several investigations of the physical phenomena, earlier results of which have been reported.[3,4] Experimental techniques have subsequently been refined to achieve quantitative data which clarify both the process and its underlying theory. This paper is the first of a series on these results.

The first effort in the investigation was directed to the simplification of experimental conditions. In the electric spark-over[4] machining process a series of high-current low-voltage discharges between a tool (cathode) electrode and a workpiece (anode) electrode gradually wear the workpiece into a desired form. Although all the significant phenomena should be observed in the wear caused by a single discharge, most experimental studies have been concerned with measurements of the cumulative effect of a very large number of discharges over a sustained period.

When the effects of many discharges in rapid sequence are superposed, numerous factors combine to obscure the physical phenomena; among these are known[4] to be redeposition of eroded material, both cathode and anode, formation of low-pressure vapor pockets, and temperature effects due either to the dissipation of large amounts of average power or

the formation of continuous discharges.[4] Furthermore, although emphasis has been placed on the distinction between anode and cathode phenomena, the discharges used in experimental studies have been oscillatory so that each electrode serves both as anode and cathode. This investigation was accordingly concentrated on the effects of single, unidirectional time-limited discharges. The experimental conditions were further limited to the effects of discharge currents in the lower range of those encountered in electrical machining processes, for reasons which will subsequently become apparent.

The test procedure involved the initiation of spark-over between prepared anode and cathode electrodes at appropriate spacings by application of voltages of the order of 50 to 1,000 volts. The circuit was arranged to deliver, following spark-over, a single current pulse of substantially constant amplitude and controlled duration at convenient values in the range of 17 to 1,500 millimicroseconds. The circuit arrangements are shown in Fig. 1. The liquid dielectric employed

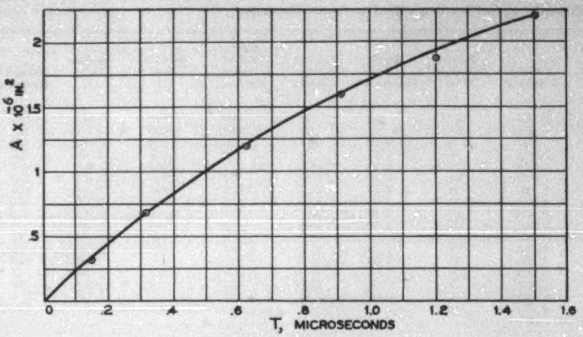

Fig. 2. Anode crater area A as function of discharge duration T for an 11-ampere discharge in materials of group 2 of Table II. Melting points over about 600 C

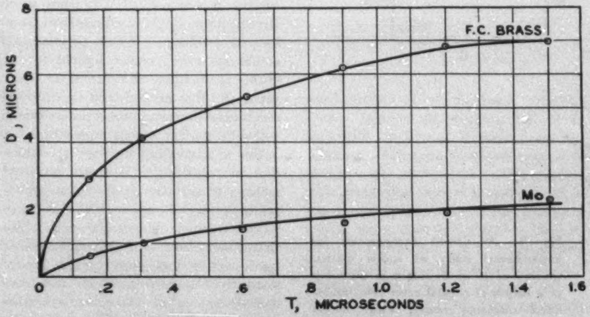

Fig. 4. Anode crater depth D as function of discharge current duration T in 11-ampere discharge for two anode materials

was kerosene from a single bulk sample. Although the chemical composition of commercial kerosene is not exactly defined, it is known that chemical composition of the dielectric has no effect on the nature of the physical phenomena in the discharge. The quantitative effect of the dielectric composition will be discussed in a subsequent paper.

The anode electrodes used were annealed specimens of metals or alloys with the properties shown in Table I. Tensile strength and resistivity values were determined by test while other properties listed are from standard references.

Although a variety of cathode materials was used, it was found that anode crater size and form are independent of the chemical and physical properties of the cathode material for cathodes with melting points over 400 degrees centigrade (C). The data reported here will include tests conducted only with higher melting point cathodes. The data obtained consist of tabulations of anode crater area, depth, and volume as functions of discharge current magnitude and duration and anode electrode constitution. For convenience many of these data are presented graphically.

First, as shown in Table II, anode crater area is independent of the anode material for a wide range of materials. Crater area has been assumed by various investigators[5] to be equal to the cross-sectional area of the electrical discharge; this conclusion is probably warranted with the relatively short discharge durations reported here. The independence of crater area with respect to anode material is thus an indication that the anode is not a significant source of ions in the discharge unless the anode melting point is low.

For the materials of group 2 of Table II, typical crater areas as a function of current duration and magnitude are shown in Figs. 2 and 3. Figs. 4 and 5 show crater depth and volume as functions of discharge current duration and magnitude for two anode materials in this same group. It is apparent from these data that although anode crater volume and depth vary with anode material these characteristics in any particular material are fairly simply functions of the discharge parameters. The data of these figures can, in fact, be described with some accuracy by an expression of the form

$$V = K_1 \times T(I)^{3/2} \qquad (1)$$

in which V, T, and I are crater volume in cubic inches, discharge duration in microseconds and current pulse magnitude in amperes respectively, and K_1, a constant characteristic of the material. Values of K_1 for a number of the materials tested are as follows:

Tungsten, 7.37×10^{-13}.
Molybdenum, 16.29×10^{-13}.
18–8 *SMO* steel, 35.2×10^{-13}.
Hot-rolled monel, 45.8×10^{-13}.
Naval brass, 58.7×10^{-13}.
17ST aluminum, 68.7×10^{-13}.
F. C. brass, 72×10^{-13}.

The relation between the physical properties of the anode material and the crater volume for a particular current magnitude and duration may be expected to cast further light on the controversial question as to the mechanism of crater formation, numerous theories for which have been advanced.[3]

For the purpose of clarifying the significant phenomena, anode crater volumes under typical conditions, for all the materials of Table I, have been plotted in Figs. 6, 7, 8 and 9 against the physical properties that have been assumed most significant by various investigators. Thus in Fig. 6 crater volume is plotted against energy required to vaporize a unit volume of electrode material initially at room temperature. Fig. 7 is a similar display of crater volume with respect to energy required to melt a unit volume initially at room temperature. In Figs. 8 and 9 volume is plotted against the inverse of the melting points and tensile strengths respectively. For the higher melting point materials there is no more than a trend towards smaller volumes as the melting temperature is increased. This trend could be a reflection of the generally higher tensile strengths of higher melting-point materials. Actually a much better correlation exists between crater volume and tensile strength and this correlation is emphasized in Fig. 10, in which crater depth is plotted against the reciprocal of tensile strength. From this curve it may be deduced that the value of K_1 in equation 1 can be computed for materials with melting points over 600 C as, approximately

$$K_1=\frac{0.44\times10^{-8}}{K_T} \qquad (2)$$

in which K_T is the ultimate tensile strength of the material in pounds per square inch. The constant is applicable to discharges in a kerosene dielectric, and, as will appear from data to follow is limited to nonferromagnetic materials.

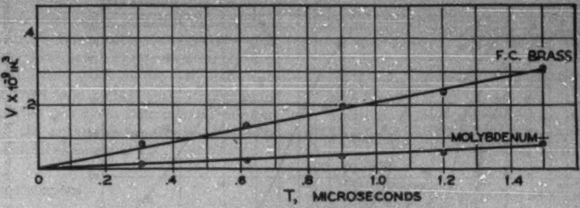

Fig. 5. Anode crater volume V as function of discharge current duration T in 11-ampere discharge for two anode materials

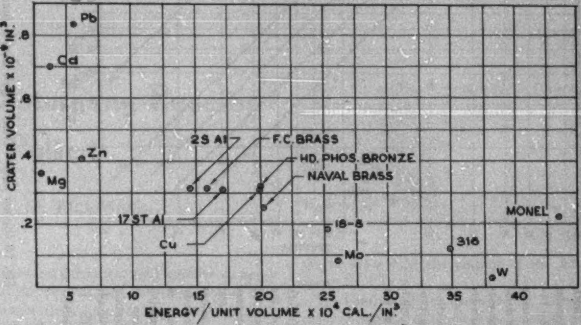

Fig. 6 (above). Volume of crater produced by 11-ampere discharge of 1.5-microsecond duration in anodes of various materials as function of energy required to vaporize unit volume of material initially at room temperature

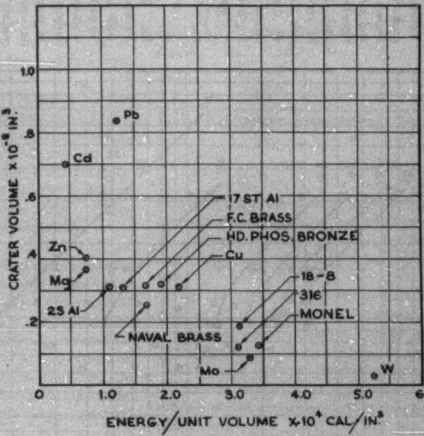

Fig. 7 (right). Volume of crater produced by 11-ampere discharge of 1.5 - microsecond duration in anodes of various materials as function of energy required to melt unit volume of material initially at room temperature

These data lead one to set aside thermal action as the primary factor in anode erosion in materials with melting points above 600 C. A question remains concerning the possibility of explosive force or a cathode "flare" action. It can, however, be demonstrated that the anode crater form is primarily dependent on the current distribution under the anode surface. This current distribution, for a given discharge area, can vary only as a result of skin effect. Skin effect in nonferromagnetic materials should be a negligible factor in the range of fractional microsecond durations of relatively small discharge currents chosen for the tests reported here; this choice was made, in part, for the purpose of minimizing skin effect, therefore emphasizing the role of

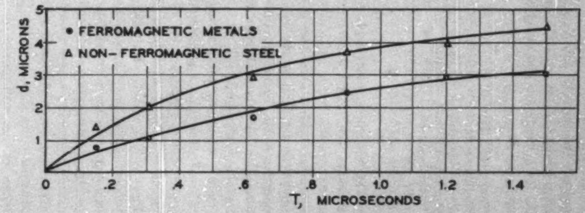
Fig. 11 (below). Crater depth d as a function of the discharge duration in a discharge of 11 amperes for ferromagnetic and nonferromagnetic materials of approximately equal tensile strength



physical properties other than conductivity. However, with a ferromagnetic material, skin effect is appreciable and the current magnitude below the anode surface is substantially decreased. The effect of a changed current distribution on the anode crater is illustrated in Fig. 11 for ferromagnetic and nonferromagnetic anodes of approximately equal tensile strength.

These data supply some confirmation for an electric field force hypothesis.[3] Moreover, quantitative data have been advanced previously to show that an ionic force can be sufficient to cause rupture.[3,4] It is possible that explosive forces play some part. Electrochemical phenomena would seem to be excluded since current (and consequently charge transported in a given time interval) appears in the expression for the crater volume with an exponent of 1.5.

Economic Design of Saturating Reactor Magnetic Pulsers

R. A. MATHIAS

E. M. WILLIAMS
MEMBER AIEE

l. 74
1
55

SATURABLE reactors have been widely applied in the electric control art. A less well-known use is in pulse-shaping or pulse-switching circuits, examples of which are to be found in ignitron trigger circuits and in modulators for high-power oscillators in radar transmitters. In the latter instance, circuits may become quite complex and there has been a need for criteria which will result in a simple design procedure. In this paper some useful relations applicable to this problem are described.

The circuit of a typical saturating reactor, or pulsactor, pulser for radar,[1] often termed a Melville line, is shown in Fig. 1. This circuit operates in the following general manner. While the source voltage rises initially, the capacitor C_1 charges through the reactor L_0. The constants are chosen so that the voltage on C_1 rises to a high value during the first cycle. For most of this voltage swing L_1 is unsaturated so that its voltage drop is approximately equal the voltage across C_1. The design of L_1 is such that it reaches a saturated state when the voltage on C_1 reaches a peak. C_1 then rapidly discharges its energy into C_2 at a rate determined by the saturated inductance of L_1. C_2 is chosen so that its peak charge is reached at the instant the energies in C_1 and L_1 are zero. C_2 is equal to C_1 in an ideal case in which there are no core losses and the following stages do not appreciably load the $C_1L_1C_2$ loop. At the instant C_2 reaches peak, voltage L_2 saturates and permits a rapid transfer of energy to the next capacitor. This process continues from loop to loop. Although all capacitors are equal, successive reactors are designed for successively reduced saturated inductance so that, by the time the energy has reached the last stage, it can be discharged into the load in a very short time interval.

The line thus acts to compress the energy transfer interval so that peak power transferred increases from stage to stage. In the ideal case (negligible loading and losses), the peak voltage from stage to stage remains constant and the peak current increases with each stage. Quite useful information on general design problems can, in fact, be obtained from an analysis based on the ideal case especially for designs using the rectangular loop materials now available. This analysis will now be made, with the further assumption that there are no interstage transformers.

The time to charge the kth capacitor C_k will be equated to the time for the kth pulsactor to go through its maximum flux swing to a saturated value. Accordingly, for centimeter-gram-second units

$$t_{k-1}=\pi\sqrt{L_{sk-1}\frac{C}{2}}=\frac{2\Delta B}{E_m}N_kA_k10^{-8} \tag{1}$$

but

$$L_{sk}=\frac{N_k^2A_k4\pi\mu_s10^{-9}}{l_k}=\frac{(N_kA_k)^24\pi\mu_s10^{-9}}{M_k} \tag{2}$$

where $M_k=A_kl_k$, the volume of the kth core.

By combining equations 1 and 2, the ratio of saturated inductances is found to be

$$\frac{L_{sk}}{L_{sk-1}}=\frac{\left(\frac{C}{2}E_m^2\right)}{M_k}\frac{\pi^2\mu_s10^7}{(\Delta B)^2}=\frac{W_m}{M_k}G \tag{3}$$

where

$W_m=\frac{C}{2}E_m^2$, the energy per pulse

$G=\frac{\pi^2\mu_s10^7}{(\Delta B)^2}$, a constant for the reactor

Equation 3 for the ratio of saturated inductances is fundamental to the design of magnetic pulsers of this type and, furthermore, offers an insight into pulser operation.

For the input stage, the inductance ratio is $L_{s1}/(2L_0)=G_1W_m/M_1$, where L_0 is the input linear inductor. Depending on the type of power supply used, G_1 may have a value slightly different than the G's for the other stages. However, for this simplified explanation, it is assumed that $G_1=G$.

Then the inductance ratio for all of the stages is

$$\frac{L_{sn}}{2L_0}=\frac{(GW_m)^n}{\Pi_1^nM_k} \tag{4}$$

This demonstrates that the core volume is directly proportional to the energy per pulse. For a given pulser, the pulse compression ratio ρ is fixed. ρ is defined as

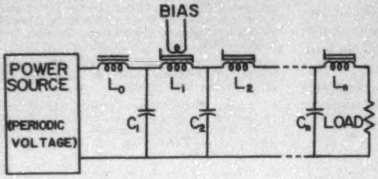

Fig. 1 (left). Basic magnetic pulser circuit

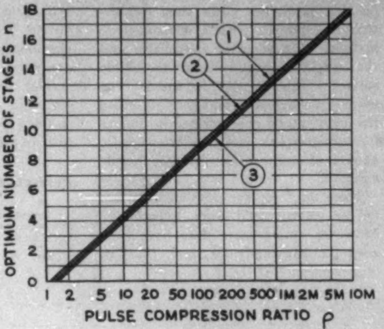

Fig. 2 (right). Optimum number of stages

Type of input:
1. Switched d-c, or half-cycle a-c per pulse with L_0C_1 tuned for maximum E_{m1}
2. Whole cycle a-c per pulse with L_0C_1 tuned to the a-c
3. Half-cycle a-c per pulse with L_0C_1 tuned to the a-c

$$\rho \equiv \frac{T_0/2}{t_{sn}} = \frac{\pi}{\omega_0 t_{sn}} \tag{5}$$

where

$$\omega_0 = \frac{1}{\sqrt{L_0C_1}}$$

$$t_{sn} = \left(\frac{e}{2}\right)^2 \sqrt{C_nL_{sn}} = \text{output pulse length}$$

Thus

$$\rho = \left(\frac{2}{e}\right)^2 \pi \sqrt{\frac{L_0}{L_{sn}}\,\frac{C_1}{C_n}} \tag{6}$$

But in the ideal case considered, $C_1 = C_2 = \ldots = C_n$. So the pulse compression ratio is

$$\rho = \left(\frac{2}{e}\right)^2 \pi \sqrt{\frac{L_0}{L_{sn}}} \tag{7}$$

This shows that, when the compression ratio is fixed, the over-all inductance and impedance ratio is also fixed and, as a result, the product of the core volumes is a constant

$$\Pi_1^n M_k = \text{constant}$$

From this it is noted that to minimize the total volume of core material to be required in the n stages, the volumes of all the cores should be equal. Or

$$M_1 = M_2 = \ldots = M_n \tag{8}$$

It is also of interest to find the number of stages required for the least total amount of core material for a given pulse compression ratio and energy per pulse. The total core volume is

$$M_T = M_1 + M_2 + \ldots + M_n \tag{9}$$

If this is minimized with respect to the number of stages n

$$n = ln\left[\rho^2\left(\frac{e}{2}\right)^4 \frac{2}{\pi^2}\right] = ln\left(\frac{2L_0}{L_{sn}}\right) \tag{10}$$

When the individual core volumes are equal

$$\frac{2L_0}{L_{s1}} = \frac{L_{s1}}{L_{s2}} = \frac{L_{s2}}{L_{s3}} = \ldots = \frac{L_{sn-1}}{L_{sn}} \tag{11}$$

So

$$\frac{2L_0}{L_{sn}} = \left(\frac{L_{sk-1}}{L_{sk}}\right) \tag{12}$$

From equations 10 and 12, it can be seen that

$$\frac{L_{sk-1}}{L_{sk}} = e \tag{13}$$

in which e is the Naperian base.

Equation 10 gives the optimum number of stages for the minimum total core material, and equation 13 shows that for these conditions the stage-to-stage inductance ratio is 2.72. Fig. 2 shows a plot of the optimums number of stages n as a function of the pulse compression ratio. Using more stages than this optimum number n is not economical, since losses are higher and more circuit components are required. In fact, the optimum design would be expected to involve somewhat fewer than the optimum number of ideal stages given in Fig. 2.

This conclusion arises when other considerations such as winding insulation and number of turns, iron and copper losses, and relative expense of associated capacitors are considered. Using 50–50 nickel-iron grain-oriented core material in a gapless type of construction, the value of G is about 1.0 in centimeter-gram-second units if the winding is close to the core. In this case, if the (ideal base) optimum number of stages are used, the least core material required is about 0.05 pound per stage per watt-second of pulse energy. The amount of core material per stage increases as the number of stages are reduced from the optimum value. However, in the case of the first stage core, the allowable copper losses and build-up of the winding may dictate a much larger than optimum size core if the volt-seconds integral to be absorbed by the main winding is large. This situation usually arises if the input is operating at power frequencies. A simple analysis of this first stage shows that the weight of core material per watt-second of pulse energy is directly proportional to the product of the input voltage and the core window area. Hence, a window of sufficient size in the first core may mean that the core volume has to be considerably larger than optimum size.

Iron losses, primarily because of the heat dissipation problems, may require

Nomenclature

t_k = time required to discharge kth capacitor
L_{sk} = saturated inductance of kth pulsactor
C_k = capacitance of kth capacitor, farads
ΔB_k = flux swing of kth pulsactor, gausses
E_{mk} = peak voltage on kth capacitor
N_k = number of turns on main winding of kth pulsactor
A_k = effective cross section of kth pulsactor core, square centimeters
μ_{sk} = saturated permeability of cross section enclosed by main winding, gausses per oersted; includes effect of core space factor, core case, insulation, and winding build-up
l_k = mean length of magnetic path of kth pulsactor, centimeters
M_k = volume of kth pulsactor, cubic centimeters
M_T = total volume of all saturable cores in pulser, cubic centimeters
W_{mk} = peak energy stored in kth capacitor, watt-seconds
G_k = a constant depending on geometry and core material of the kth pulsactor. The value usually is between 1.0 to 2.0 for Orthonol-type cores
ρ = pulse compression ratio, which is the ratio of 1/2 the period of the input stage to the output pulse duration
T_0 = period of input stage, seconds
t_{sn} = output pulse length, seconds
n = number of pulse compressing stages in the pulser

that the last few stages have smaller core volumes or special heat dissipation means. Another requirement is that, for maximum transfer of energy from one capacitor to the next, the capacitors increase in value inversely as the stage efficiency. This also implies that the peak voltage from one capacitor to the next drops in direct proportion to the stage efficiency.

Using the design principles outlined here, a magnetic pulser may be designed and the actual operating voltages and currents can be predicted with moderate accuracy. In some cases, transformer stages may be required to transform voltage level or impedance level since, when the input and output impedance levels are fixed, the compression ratio fixes the impedance ratio of the two unless linear interstage or saturable transformers are utilized.

Telephone Lines for Rural Subscriber Service

LESTER HOCHGRAF
NONMEMBER AIEE

R. G. WATLING
ASSOCIATE MEMBER AIEE

Synopsis: The cost of supplying telephone service to rural subscribers is high in large part because of the high initial cost and the maintenance of outside plant required to serve the subscribers. For the immediate future the most promising methods of reducing these costs are by new and cheaper methods of line construction and by concentrating the load on fewer pairs rather than by other types of transmission such as radio. Some Bell system developments now under trial to reduce the cost of line construction and to increase the load capacity of existing lines are described. The problems of carrier transmission in rural plant are discussed with emphasis on overall cost reductions which may be obtained by the use of the transistor and the compandor circuit.

IN THE rural areas they serve, the Bell system companies for many years have had as a major objective making phone service available at a reasonable price to every resident. Since the war over 2,250,000 Bell telephones have been added in rural areas. In doing so the companies have:

1. More than doubled the number of telephones in Bell rural areas.
2. Added telephones at the rate of over 1,000 every working day.
3. Added switchboards in many places and constructed many new buildings.
4. Spent around $750,000,000 to extend and improve service.

In addition to extending lines to families with no telephone service, considerable progress also has been made in improving the quality of rural telephone service. To help make such good progress possible, much development work has been done on new materials, methods and tools.

Open-wire and cable pairs are the types of facilities generally used to supply telephone service to rural subscribers in sparsely settled areas. Other means of transmission have failed to gain wide use because of the high initial cost of the equipment, the necessity for skilled maintenance, or because of expensive power supply arrangements needed to provide a dependable source of electric energy to the terminal equipment. Work is continuing in other fields, but for the immediate future it appears more promising to consider new and cheaper methods of building rural lines as well as the use of equipment, such as carrier systems, which will pemit more extensive utilization of outside plant facilities.

Probably no one method of construction nor any single new development will yield a large reduction in rural plant costs, but there are situations where different types of construction or new transmission arrangements can, and will, show cost savings. If advantage is taken of all such situations, the aggregate saving can be large and can make possible further rural plant extensions to serve new applicants for telephone service. Such a program is not glamorous, but it is necessary and is a challenge to the best brains that the industry can supply.

The rural telephone layout resembles a water shed map. Beginning at a small central office, nowadays usually a dial office, cables may radiate and serve nearby subscribers. As these cables become smaller in size, there comes a point where it is more economical to construct an open-wire line. Such a line might start with two or more crossarms of wire and taper in size as branches and taps serve subscribers. Finally, at the ends of the network, two and even single pair lines serve the more remote subscribers. Such a layout must include not only the distribution plant but the trunk circuits which tie the office to the system network.

At the close of World War II, the rural plant was made up largely of steel wire on pole lines having span lengths up to about 250 feet in heavy storm-loading areas. Steel line wire of the *109* size, good for these span lengths, had been made available in 1934. In 1937, a higher strength steel line wire *109H* was developed and span lengths of 350 to 450 feet were then practicable, the length of span depending on the storm-loading area. Zinc coatings applied by an electrolytic process which permitted coating weights two or three times those of hot dip coatings came into use in 1934, with consequent increase in life expectancy of steel line wire.

Although steel line wire provides a satisfactory transmission equivalent for the average rural line, a few of the open-wire pairs on some rural leads cover the longer than average circuits and for these a wire of higher conductivity must be provided. Copper is satisfactory from the transmission standpoint and is used where necessary, but its size and cost become prohibitive when it is made strong enough for long span construction. To care for this, copper-steel line wire (conductivity 40 per cent of that of the same diameter in copper) is used.

In 1946, extra high-strength steel line wire *109E* and a larger diameter steel wire *134H* of lower resistance were introduced. Both of these wires are good for maximum span lengths of 600 feet in heavy storm-loading areas, as contrasted

Paper 55-229, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted August 2, 1954; made available for printing December 8, 1954.

LESTER HOCHGRAF is with the Bell Telephone Laboratories, Inc., New York, N. Y., and R. G. WATLING is with the Bell Telephone Laboratories, Inc., Murray Hill, N. J.

to 350 feet for *109H* and 250 feet for *109*. Also, in 1947, a higher strength copper-steel wire (for use in spans up to 350 feet) was made available. This wire can be used when lower resistance is needed for transmission or signaling reasons.

The 600-foot span, which *109E* and *134H* wires make possible, is used by the Bell system operating companies not only in joint-usage pole lines carrying both telephone and power circuits but also in pole lines carrying telephone circuits only. It is pertinent to note that each pole eliminated from a line by using long span construction may represent savings of the order of \$30 to \$40 in first cost. The difference in wire costs is relatively small, about \$3 and \$20 per circuit-mile more for *109H* and *109E* respectively, as compared to plain *109* steel wire. The costs of copper-steel and of copper wire are approximately twice that of steel, but where transmission requires a facility better than steel, the use of copper-steel wire with long span construction results in a considerable saving in construction costs over that of solid copper wire.

Typical lengths of rural lines in various sections of the country range from 8 to 12 miles and in some instances extend as far as 25 to 35 miles in very sparsely settled areas. Such lines are not exempt from maintenance and transmission difficulties. The transmission and signaling qualities of long circuits are sometimes impaired during periods of rain, fog, and sleet because of insulator leakage. On the older rural lines, use of transpositions may be infrequent, with consequent prevalence of high circuit noise which has occurred as rural power networks have been extended. To control circuit noise and crosstalk when two or more pairs exist on a line, it is necessary that the circuits be transposed at certain intervals and in a prescribed manner. To be effective, the transpositions must be properly installed; such correct installation costs both time and effort.

Transposition Arrangements

Several transposition patterns have been developed over the years, such as the *ABC* system, the exposed line system, the *N* system, and the more recent *R1* system. The earlier systems employed "drop bracket" transposition assemblies to provide sufficient clearance between the wires when the plane of the wires was turned through 180 degrees. These transpositions require two spans to complete. The configuration causes a crosstalk irregularity which is appreciable when transpositions are closely spaced. A typical drop-bracket transposition is shown in Fig. 1.

The *R1* transposition system makes use of a tandem transposition bracket of the type shown in Fig. 2 or other "flat" type of transposition hardware. This provides a point-type transposition that can be "thrown in" easily after the wires are tensioned, thus providing some economies in construction. The *R1* design is characterized by having a transposition in each pair on alternate odd, or even, poles. This simplified design is relatively easy to administer in the field. The *R1* system is the present standard for rural line construction in areas relatively free from fog and sleet. It has given great improvement with respect to circuit noise as compared to the older designs. However, some service troubles may be experienced on tandem transposed lines in areas subjected to high winds and excessive precipitation. Under these adverse conditions, the use of a newly developed 4-inch point transposition assembly is recommended. This assembly retains the good features of tandem construction and provides a reduction of as much as 10 to 1 in leakage and greater freedom from wires contacting.

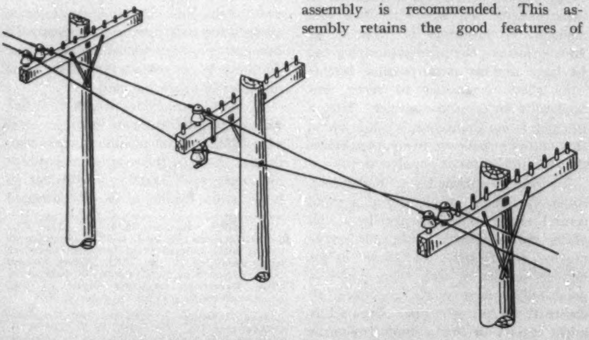

Fig. 1. Drop-bracket transposition

Rural Distribution Wire

Recently, a 6-pair wire facility has been developed for use principally in rural areas. This wire, known as rural distribution wire, finds its principal advantage in low material and construction costs and is intended primarily for use in reinforcing open-wire lines, particularly in locations where the addition of another crossarm would require pole replacements. The wire consists of six twisted pairs of individually insulated 19-gauge copper conductors, stranded around a polyethylene insulated *109E* steel line wire which serves as a support member. The copper conductors are insulated with high molecular weight followed by a jacket of polyethylene polyvinyl chloride compound which offers better resistance to abrasion than does polyethylene alone. The polyvinyl chloride compound is colored to provide ring, tip, and pair identification. Fig. 3 shows the method of fastening the rural distribution wire in a special pole-mounted bracket.

Suspension-Type Line

More recently attention has been directed by the Bell Telephone Laboratories to the development of a light open-wire line especially for use in sparsely settled areas. This line, designated the "suspension" type, employs the lightest materials consistent with good construction practice, and eliminates or simplifies many labor operations. Features of the new line are shown in Figs. 4 through 8. Substantially, all work incident to line construction is performed from the ground, thus virtually eliminating the necessity for pole climbing during line construction. Poles are equipped with pole brackets or crossarms, insulators, transposition brackets, and guy attachments before they are erected. Crossarms are bored to carry two or four pairs of wires. The suspension insulators are mounted underneath the crossarm, except at transposition positions, and are so designed that wires can be installed in them from the ground with a special lifting tool. Before the wires are raised to their insulators, vibration dampers are placed on each wire in each span. The damper is a short length of plastic tubing split helically along its length to facilitate its installation on the wire. This damper, by its flexing action as the wire moves under wind-induced vibrations, will absorb energy as fast as the wind puts energy in, thus damping out high-frequency low-amplitude vibrations which might result in injury to the wire at the point of its support. The damper is effective at any position on the wire in the span.

The wires are transposed by means of a simple repetitive transposition scheme. The line has been designed to provide up to four circuits at voice frequencies, which affords sufficient capacity to serve many rural areas. In those cases where more circuits are required, carrier systems could be used on some of the pairs. This line is still in the field trial stage, and it will be some time before advantages of the new system can be evaluated with certainty.

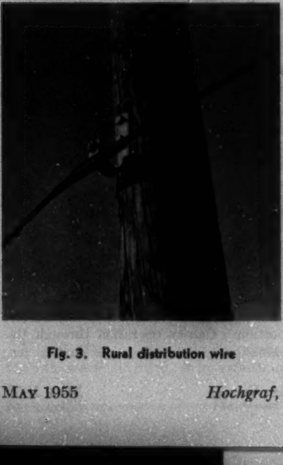

Fig. 3. Rural distribution wire

Carrier Possibilities

Two general means of concentrating traffic in the wire plant have been proposed and are under study. One is to obtain additional channels by frequency or time division means (carrier) and the other is to move switching devices closer to the subscribers and to give each subscriber access to more than one central office circuit.

Carrier possibilities for rural use have improved in the last few years by the development of the compandor, a circuit arrangement which provides a degree of immunity against noise and crosstalk, and by the development and availability of the transistor which offers exciting possibilities for reducing size of equipment and power supply requirements.

Subscriber carrier channels have already had some use in the Bell system. These channels were obtained by means of the type-*M* carrier system which provided one to five channels on a power line. Later modifications made it possible to use the *M* system on telephone pairs, but this use was limited by crosstalk to five channels per pole line. At present, about 10,000 rural subscribers are served by *M* carrier systems, some operating on telephone and some on power line facilities.

If it develops that carrier costs are reduced so that carrier channels can be used extensively, lines can be built with fewer pairs; fewer pairs can mean lighter line construction resulting in cost savings above those caused by the actual reduction in number of wires. Carrier channels would also be of particular value as a means for obtaining additional circuits on an existing line where it may not be possible to add more pairs without rebuilding the line.

It is not a simple problem to design, build, and operate a rural carrier system which can show substantial savings over wire distribution methods, even for the cases most favorable for carrier use. Such cases would be where the subscriber load is relatively concentrated and where the hauls are at least 4 or 5 miles long. Carrier transmission may be of particular value where it can defer major construction which would be required if voice frequency transmission were used.

Part of the high cost of present carrier systems suitable for rural use is the necessity for providing dependable power to operate the vacuum tubes in the terminal equipment. Where the carrier terminals can be located in telephone offices, this is not a severe problem but where, as in a rural subscriber carrier system, the carrier terminals must be remote from the office, this power supply problem may be a deciding factor. With the transistor now available, the hope is that the power requirements can be reduced to very modest values. It may be possible to supply stand-by power to transistors by cheaper methods than are possible where present vacuum tubes are used.

Fig. 4. Mounting crossarm on pole for suspension-type line

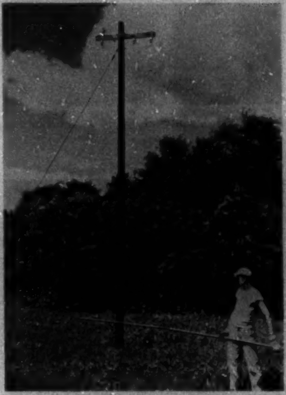

Fig. 5. Pole erected on suspension-type line

Transmission Characteristics of Rural Line

Possibilities of using carrier channels on existing rural plant vary from line to line. The extensive use of steel wire is an unfavorable factor because the carrier attenuation of steel wire pairs is relatively high. It is about ten times higher than for copper pairs which are used for toll carrier systems. Fig. 9 shows losses for *109* steel wire pairs and for copper-steel

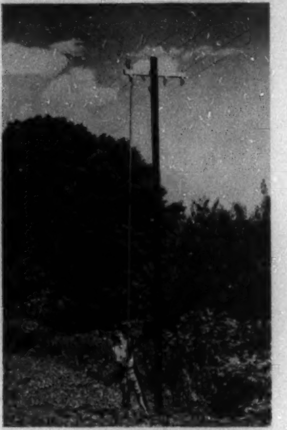

Fig. 6. Tightening of insulators on suspension-type line

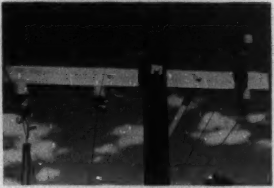

Fig. 7. Crossarm of suspension-type line with wires in place and being placed

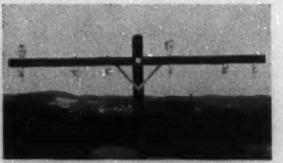

Fig. 8. View of suspension-type line with all wires in place

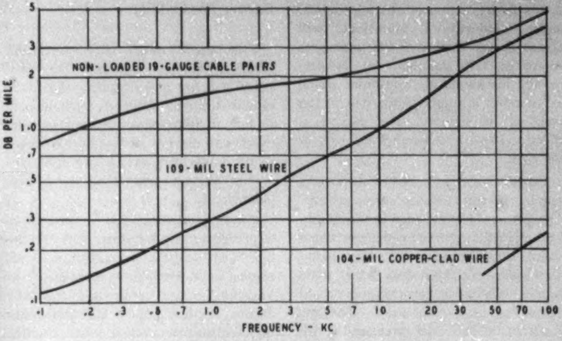

Fig. 9. Attenuation of typical wire circuits for rural carrier

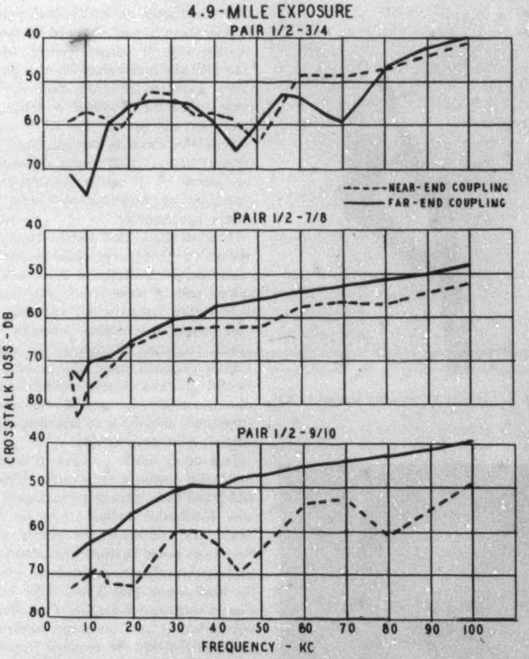

Fig. 10. Typical measured crosstalk couplings between R1 transposed pairs

pairs. A carrier system can be built to take care of line losses up to 30 to 40 decibels without repeaters. Carrier circuits on steel wire can be utilized for reasonable distances either by limiting the frequency band to that just above voice where attenuation is small, or by using repeaters or line amplifiers which, unfortunately, are themselves power-consuming devices. Where copper or copper-steel wire is used for voice transmission reasons, the carrier loss is low. On such pairs, the open-wire loss at carrier frequencies is not a significant factor for the distances involved in most rural circuits. However, most rural lines pass through a section of cable on the way to the central office.

It would, of course, be quite desirable to operate the cable portion of the circuits on a carrier basis as well as the open-wire portion. Carrier operation through the cable permits locating one carrier ter-

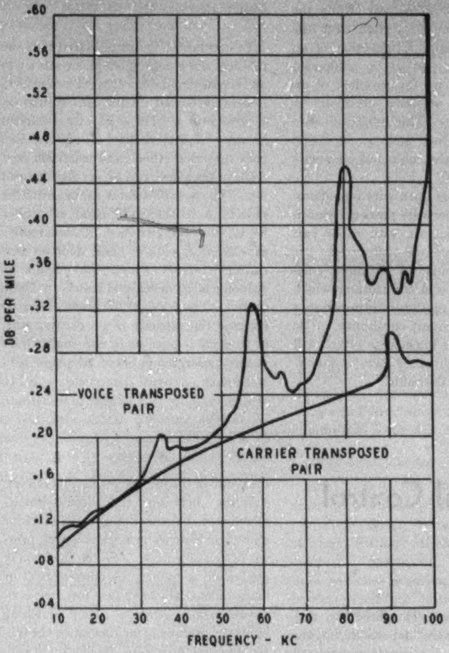

Fig. 11. Absorption losses of voice and carrier transposed pairs

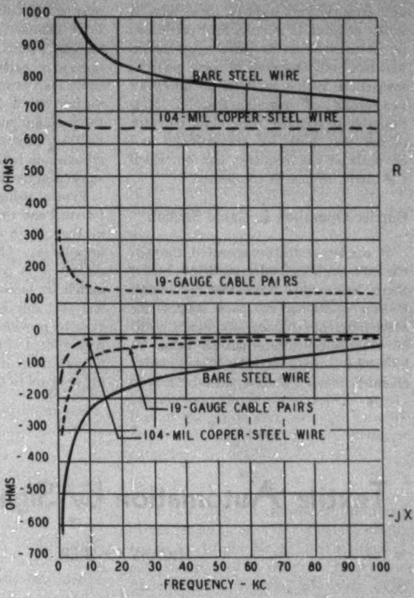

Fig. 12. Characteristic impedance of open-wire and cable pairs

minal at, or near, the central office and saves cable pairs as well as open-wire pairs. The carrier attenuation of cable pairs is quite high, as shown in Fig. 9. If the cable section is long, the result may be a carrier system in which the major part of the transmission loss is in the cable section, while the major savings are to be found in the open-wire portion of the circuit.

A favorable frequency band for carrier development is in the range from about 8 to 150 kc. The lower frequency is limited by the need for adequate frequency separation from the voice subscribers. The upper end is limited by the increase in attenuation, crosstalk, and possible interference from power line carrier systems and radio circuits. However, using this frequency band requires co-ordination with other carrier telephone systems operating on the same lines and using the same band of frequencies.

Crosstalk Considerations

It will often be desirable to operate more than a single rural carrier system on a line. In fact, it would be quite desirable to be able to apply carrier systems to any or all pairs on a line. Such operation is limited by crosstalk coupling between pairs. On most lines the pairs have been transposed only for voice operation.

Without compandors the crosstalk loss between line pairs should be held to the order of 60 decibels. With the voice transpositions, this value can be obtained only for frequencies just above the voice band or between those pairs that are well separated, as from one side of the pole to the other.

Compandors give a 20- to 25-decibel advantage against line crosstalk coupling. Where they are used, the coupling requirements are considerably relaxed and there is a great deal more freedom in the possible application of carrier channels to rural lines. Thus, the field for application of rural carrier will be enlarged by the development of a cheap compandor.

The rather general installation of *R1* transpositions in new rural plant is favorable to carrier development. A well-constructed *R1* transposed line can be counted on to provide two pairs on the top crossarm with low crosstalk coupling for carrier use up to 100 kilocycles per second on circuits up to 10 miles long with compandors. On any particular line, more pairs than this may actually be usable. Where it is desired to be certain of more pairs for carrier use, or where longer distances are involved, recently developed simple modifications of the *R1* design can be used. These modifications substantially decrease the crosstalk coupling.

Typical values of crosstalk coupling measured on an existing *R1* transposed line of good quality are shown in Fig. 10. For some carrier systems now under study, which use compandors, the crosstalk coupling should be better than about 40 decibels. This requirement depends very much on the system characteristics and on the level differences which are permitted to exist between the same frequency channels of carrier systems operating on different pairs.

On older lines, transposed 20 or more years ago, conditions may not be so favorable for carrier use. Because of the wide variety of transposition designs and arrangements used on these lines, it is not possible to make a firm prediction about these types of pairs. Absorption loss has been observed in some pairs at frequencies as low as 20 or 25 kilocycles per second, as shown in Fig. 11. It is desirable to measure these older pairs for carrier use, both for transmission and crosstalk, in the frequency band in which the carrier system is to operate.

Carrier Operation in Cable Section

If carrier is to be operated through the cable section, as discussed previously, there are some additional problems. Carrier operation on pairs loaded for voice frequency transmission is not possible since such circuits cut off below 10 kilocycles per second. The carrier channels in such a case must be routed over a nonloaded cable pair, while the voice channel may be routed over the original loaded pair. Connection of an open-wire carrier pair to a nonloaded cable pair brings up the problem of reducing the high reflection occurring at the junction point. This reflection leads to transmission loss and to increased crosstalk in both the cable and open-wire sections of the line.

Typical values of open-wire impedance for steel and copper wire pairs are shown in Fig. 12 in contrast with cable pair impedance. Above 30 kilocycles per second it is possible to obtain a good match by means of a transformer which will probably be of the autotransformer type to provide circuit continuity. The requirement of the impedance match will not be stringent but some form of matching appears to be desirable.

Conclusion

In conclusion, it can be stated that the problem of furnishing telephone service to an increasing number of rural subscribers is being attacked by the Bell system on several fronts. These include a careful scrutiny and a review of present line construction methods and materials, and trials of lines designed especially for rural use. The possible field of use of switching devices to concentrate rural subscriber loads is also being studied. Concurrently, experimental work is being done on new carrier systems which may make it economical to develop channels by these means. These might be used either to increase the capacity of an existing line, or to make it possible to use smaller lines to serve a large number of telephone subscribers.

Textile Automation by Signal Control

LOUIS CASPER
MEMBER AIEE

IN THE field of electric control of automatized machines, much effort is being directed towards co-ordinating the thinking of engineers in the mechanical field of design[1] and in the electrical field of signal communication.[2] One of the problems dictates the evolution of a common vocabulary. Closely related to it is the matter of making available to engineers in each of the two fields the body of knowledge already available in the other. These twin problems are discussed for a specific, typical situation.

The experimental development to be described looks to the general control of textile machinery by means of ordinary 5-unit, binary-coded paper tape and standard associated printing-telegraph apparatus[3] which are applied with minor alterations. A successful experimental model of an embroidery machine has been found capable of responding to tape control at the average rate of 500 stitches per needle-minute—the color, direction, and length of each individual stitch having been put under anticipatory control during the brief time interval separating each stitch from its precedessor. The development also contributes by specific example to the notion of the automatic factory in which unit machines may be ganged together and remotely controlled for purposes of labor economy and maximum machine-hour utilization.

Objectives

Because in this adaptation, as in previous typesetting-machine[4] and computer[5] applications, the control equipment has been lifted bodily out of a telegraphic environment, the remoteness of the control of single or ganged machines may be anywhere—at the units themselves, in one corner of the factory work room, floors below, or from an office or studio miles away. The last-mentioned capability is derived from the reproducibility of 5-unit telegraph signals by standard methods of tape reperforation, now technically feasible throughout the world by wire, cable, and radio transmission.

Granted that extreme remoteness of control, however practicable, may for the moment be brushed aside by today's textile practitioners as being somewhat in the realm of the future, yet flexible electric coupling between the needle-shuttle-fabric-feed structures of a textile machine and their controls remains a useful, present design objective. So too the ideal of electrically switching together several or many identical machines for common, simultaneous operation. Here switching holds the promise of emancipating the textile manufacturer from the burden of providing each one of a battery of machines with individual card or link-pin controls and from his present inability to deploy his facilities quickly to meet an influx of orders with their urgency priorities.

The Textile Machine Approach

Even in their modern forms, both weaving looms and embroidery machines tend to be heavy, ponderous, and inflexible because of the rigidity of their systems of control pins, rods, gears, cams, and pantographs, which must be mechanically coupled to the functional parts of the machines. When the controls are electrical, a relatively few solenoids interposed in the gears and shafting between driving motors and the actuated needles and fabrics suffice to impart to the latter all necessary movements in lieu of mechanical ties. The sequencing of the solenoids is adaptable to reliable methods of electric machine switching with its advantages of flexibility and speed.

EMBROIDERY IN COLOR

Textile embroidery usually uses a woven fabric as a base upon which the design is added as an embellishment. The

Paper 55-174, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing December 22, 1954.

LOUIS CASPER is with the Electrotext Corporation, New York, N. Y.

The author wishes to express appreciation to J. J. Fossaner, R. B. Benedict, and L. D. W. Casper for design and construction work in connection with the development.

machine resembles the familiar sewing machine in its needle movement. The fabric held in vertical movable frames and receiving the embroidery design must be positively positioned in sequential presentation to horizontal needles and their associated shuttles, loaded with colored or textured thread or yarn.

In the experimental machine, provision has been made for the initial use of ten different colors of thread. A compact row of ten horizontal needles in the *z* axis backed up by their corresponding ten shuttles (the operation of which can be separately selected for control) are rack-powered by a single drive designed for a $2^1/_2$-inch needle throw.

FRAME CONTROLS

In a vertical plane of the *x* and *y* axes which is interposed between the horizontal row of needles in front and the row of shuttles in back, the piece, or roll, of base fabric upon which the embroidered design is to be created is affixed semi-permanently to a pair of lead-screw driven frames running on guide rollers. The outer frame moves horizontally, to and fro, along the *x* co-ordinates in controlled steps equal to the chosen length of stitches and carries the vertical frame with its drive motor and lead screw. The counterbalanced inner frame moves vertically, up or down, along the *y* coordinate in stitch-length steps.

CONTROL BOXES

The codification of frame controls to accomplish stitching in 16 directions is simplified by the mechanical design of the power trains to the lead screws. Control boxes of identical pattern are interposed between horizontal and vertical frame drive motors and their respective lead-screws. In each control box are clutches and gear trains which perform two functions in response to electromagnetic controls: The lead-screws' progression, or the reversal thereof, is controlled by two clutch-trip magnets, either one being code selected for each frame movement; and the lead-screws' progression can be halved or restored to normal by two shift solenoids which are code selected to couple together, until reshifted, two pairs of matched gears in tooth ratios of 2-to-1.

By these means, a codified control tape advances the frames one step at a time in either direction, horizontally and/or vertically, in full- or half-stitch increments, as desired. In combination, the vertical and horizontal codes also advance the design in either direction along any one of six diagonals by simultaneous shifting of the frames in full- or half-stitches along both the *x* and *y* co-ordinates.

Table I. Directions of Needle

Direction	Vertical Movement	Horizontal Movement
Idle	none	none
N	up, full	none
NNE	up, full	right, half
NE	up, full	right, full
ENE	up, half	right, full
E	none	right, full
ESE	down, half	right, full
Etc.	up or down full or half	right or left full or half

DIRECTION OF MOVEMENT

The directions of relative movement of any fixed needle with respect to the changing position of the inner, vertical frame may be conveniently thought of as 16 compass directions from a datum point, as shown in Table I.

UNISON POSITIONING

One or the other of the end needles must have a home position, say at a corner of the design, from which it will be stepped, without stitches, to the point where the design will be begun. Area limit switches guarding the four design borders facilitate initial homing in a corner: The insertion in the coded tape of more than enough control steps towards the edges to pass the two border limit switches defining a corner will place a gang of machines in unison positions for commencing a new design, no matter what their respective locations may have been after previous use.

NEEDLE CONTROLS

All ten needles are normally retracted and latched in an inoperative position until released individually by coded signal. When all needles are latched, the fabric can be stepped by operation of the frames into position under the needle next to be released by the code tape control. When so released, the needle and its associated shuttle movement will produce one stitch.

SEVERANCE OF THREADS

The needle and shuttle threads are, in response to the tape control signal, severed close to the fabric on both sides of the workpiece.

COLOR CHANGES

Severance of needle and shuttle threads without human intervention and without loss of time beyond that of a single stitch facilitates ready changes of color in design since, to resume stitching, it is only necessary to serve the work horizontally (without stitching) to a needle shuttle loaded with thread of a proper color and then to release it.

POSITION CHANGES

The frames will also, in effect, transfer a needle, after retraction and severance of thread, from its former position to a desired new position anywhere on the workpiece.

TYPES OF STITCH

The prototype machine uses a lock-stitch reciprocating shuttle which, as in the familiar home sewing machine, locks, with a second thread, the loop introduced through the fabric by the needle and prevents its withdrawal with the needle. It is beyond the province of this paper to list the many textile variants for the insertion of thread or yarn through material which may vary from fine silk to heavy carpeting.

MATERIALS

Thread usable in embroidery machines of this type may be of any standard weight or gauge; it may be made of synthetics, silk, cotton, wool, or mixtures, from single filaments to heavy multiple-twist. The backing of embroidery may range all the way from flimsy gauze to burlap and canvas and range in shape from squares to belts to made-up garments.

LENGTH OF STITCH

As noted in the foregoing, the length of stitch is under continuous 2-to-1 codification in the machine. In addition, it is also adjustable, by presetting, from 4 to 32 stitches per linear inch.

The Printing Telegraph Approach

Five levers, each capable of taking up either of two positions, can determine 2^5, or 32, different code control combinations. These 32 combinations are sufficient to select and actuate any one of a combination of 26 different needles and associated shuttles, retract and relatch them, sever all threads, and halve the normal length of stitches.

There is a striking similarity between such control requirements and those met by a conventional teletypewriter. In the latter case, the same 32 code combinations are available; there are 26 different alphabetic type bars to be actuated, one at a time. The remaining codes are used to control the movement of the typewriter carriage and shifts between upper and lower cases.

Analogies

It was the similarity of telegraph communication art to the textile control problem which first suggested the probability that available telegraph equipment, with only minor adaptive changes, might be applied directly to the control of embroidery machines. In both cases, e.g., long 5-unit tapes can be code punched on keyboards (the telegraph perforator); they can be stepped along by means of punched out feed holes, one control code (the telegraphic letter) at a time, scrutinized by five transverse, ganged sensing levers (the telegraph transmitters' tongues), bearing electric contacts for making circuits (telegraphic marking), and breaking them (telegraphic spacing signals).

The Distributor

In action, telegraphic distributors are not unlike those of automotive ignition, with revolving arms sweeping sequential segments. In telegraphy, where miles separate perforator keyboards from terminating teleprinters, two additional commutator segments must be added to the five signalling segments to maintain necessary start-stop synchronism between the distributor brushes at the sending and receiving ends of the wire. These extra two segments, total seven, are usefully retained in textile control: first, to mark the time and set the operating pace in stitches per minute; second, to schedule and synchronize the related electrical events which must precisely dovetail; and third, to shift control from the 7-segment signalling channel just described and hereafter called the *B* channel, to a similarly contrived *A* channel having seven more segments; hence, a total of 14 segments during each revolution of the brushes before the entire cycle repeats. In telegraphy, the *A* and *B* channels are alike in function as well as in arrangement, and they transmit two different telegrams. In the embroidery machine, the two channels are different in their functioning: channel *A* governs the operation of the frames; and channel *B* governs the operation of the needles.

Two-Channel Operation

The necessity for a second channel in textile operation arises partly from the fact that the *B* channel's 32 code combinations have been exhausted in controlling the needles and, beyond these 32 combinations, there exists a further requirement for codes to position the frames carrying the fabric. Neglecting variable lengths of stitch, which have already been provided for on the *B* channel, frame movements require nine additional code combinations (including one for no frame movement). Another channel *A* is therefore required. Since three levers (affording 2^3-8 codes) are too few, a minimum of four levers is required for the *A* channel. It simplifies design to employ five levers instead of four, making channel *A* identical in form (though not in its functioning) with channel *B*, and making it possible to use the existing 2-channel, start-stop telegraph apparatus with little change.

There is another reason why the 2-channel telegraph adaptation proved attractive in textile control. The needles must be idle while the fabric is being moved and the fabric must be held steady while the needles pierce it and are withdrawn. Alternate, i.e., 2-channel, operation is the answer. As the distributor brushes sweep the first seven segments, the frames are moved to a new position. As the brushes sweep the second seven segments, the needles and shuttles accomplish one stitch.

At only one point has it seemed expedient to have the textile application depart from 2-channel telegraph practice. In the latter, telegrams on *A* and *B* channels are independently perforated in separate tapes by separate operators and are fed into separate transmitters. In textile control, it was evident that a single tape, fed through a single transmitter, was mandatory to preserve co-ordination between frames and needles. Therefore, alternate switching of the tape codes takes place—first frame function, then needle function; frame, then needle—*A* channel, then *B* channel, etc., as the tape progresses through the transmitter, center hole by center hole. There are therefore two center holes per stitch; two equal control-time intervals per stitch (seven segments, five code units); and two coded controls (frame, needles) per stitch.

Integration of Functions and Controls

Circuitry

Impulses through segments on the frame control channel actuate directly the trip magnets in the lead-screw control gear trains. Impulses through segments on the needle-shuttle selection and control channel actuate a series of five multipoint, single-pole, double-throw relays arranged in a fan or tree circuit in such a way as to find 16 different paths for the applied potential to take to trip, retract, and otherwise to control ten needles. In the experimental model the first of the five single-pole, double-throw relays has one pole idle; if utilized, the number of paths through the circuit could be increased by 16, and the total number of needles (and thread color changes) could be increased to 26.

A comparative sequence of the usage of 14 segments on 2-channel start-stop distributors and of embroidery machine control is now given:

In 2-Channel Telegraphy

1. Start.

2, 3, 4, 5, 6. Channel-*A* intelligence. 32 combinations, levers 1 to 5.

7. Stop.

1′. Start.

2′, 3′, 4′, 5′, 6′. Channel-*B* intelligence. 32 combinations, levers 1′ to 5′.

7′. Stop.

In Embroidery Machine Control

1. Start. Tape rests with *A*-channel punched holes over levers.

2, 3, 4, 5. Strapped for control of frames. During interval, frame relay and special secondary tripping circuit transfer any information on:

> Lever 1 to move vertical frame up.
> Lever 2 to move vertical frame down.
> Lever 4 to move horizontal frame to right.
> Lever 5 to move horizontal frame to left.
> Lever 3, if operative, renders levers 1, 2, 4, and 5 inoperative. Used to blank frame channel. Possible combinations: 1, 2, 4, 5, 1–4, 1–5, 2–4, 2–5, 3. Combinations not used: 1–2, 4–5; three pulses and up; five spacings.

6. Not used.

7. Steps tape, placing *B*-channel punched holes over levers.

8. Not used.

9, 10, 11, 12. Strapped for control of needles. During interval, needle relay and special secondary tripping circuit initiate stitching cycle, after having set up a 16-branch fan circuit controlled by levers 1 to 5 through relays as follows:

1. Levers 1–2–3–4–5 to release needle shuttle 1.
2. Levers 1–2–3–4 to release needle shuttle 2.
3. Levers 1–2–3–5 to release needle shuttle 3.
4. Levers 1–2–3 to release needle shuttle 4.
5. Levers 1–2–4–5 to release needle shuttle 5.
6. Levers 1–2–4 to release needle shuttle 6.
7. Levers 1–2–5 to release needle shuttle 7.
8. Levers 1–2 to release needle shuttle 8.
9. Levers 1–3–4–5 to release needle shuttle 9.
10. Levers 1–3–4 to release needle shuttle 10.
11. Levers 1–3–5 to retract all needles and sever all threads.

Ganged Machines

A cord-patching and switching panel is provided so that any one transmitter-distributor, out of a number of such, may be manually plugged up to any selected one or a multiplicity of embroidery machines, thus affording production flexibility and capacity to meet manufacturing demands.

Maintenance Costs

It is a feature of electric control, as opposed to mechanical control, that the patching board, transmitters, distributors, and switching may be concentrated in a lint-free location as remote as necessary from the machines proper. Interpretive neon lamps introduced into the circuitry facilitate electric servicing of a battery of machines; and machine concentration reduces testing and regulating labor requirements.

Since the electric equipment has seen long service in the telegraphic art, low costs for electrical maintenance may be reliably forecast, even in advance of factory application. Labor saving should be experienced in the mechanical maintenance department by elimination of cam and other relatively complicated mechanisms. Because of their reduced size and complexity, electrically controlled machines should cost less, produce savings in floor space requirements, and should consume less power.

Manipulation

Embroidery design is primarily a work of art. In textile manufacture the artist has the additional economic obligation of catering to the capabilities of his machine. In achieving beauty he must also choose a means of utilizing time most efficiently in presenting his fabric to the proper needles.

The artist, therefore, carefully makes in color a cross-section paper layout of the routes his needles must take to execute his pattern. From this layout, via a code schedule sheet, a keyboard operator punches tape, translating colors and needle routes into coded control signals.

Punching Tape

The textile keyboard, while still of telegraph standard tape-perforator design is, of course, no longer tied to the Roman alphabet. Its key caps are replaced with new ones designating the frame and needle controls; and internal changes governing punch block pin selection are made to secure for the operator a natural left- and right-hand cadence in controlling needles and frames. The operator must insert the necessary controls for frame movement where no stitching occurs, or where the artist has designated backtracking or stitch overlaying for special texture effects.

Short Cuts

Often-repeated coded tape sequences, such as those which guide the frames so that a needle stitches outline circles of various diameters or inward or outward spirals for delineating rings, become subjects for the advance preparation of template tapes and for their insertion in the master tapes at proper points to save the artist's and operator's time. Both men would naturally develop other cooperative short cuts. The preparation of control tape, though the means by which this machine achieves its versatility, is an exacting detail of manufacture.

Playback

Future experience may show that the principles of playback may supersede the described division of work between artist and keyboard operator. Before playback, the artist would use a standard arythmic teleprinter keyboard to create the original design in thread or yarn directly on the fabric. The tape, for reuse and duplication, would be produced as a by-product record of his original design.

Duplication of Tapes

The perforator is capable of producing more than one tape at a time, and by means of reperforators a tape may be used to reproduce any number of copies of itself economically. Paper tape may be run through transmitters scores of times before wearing out. Parchment tape is available, having life running into hundreds of occasions of reuse.

Multiple Patterns

In certain pattern designs advantage is taken of the needle flexibility afforded by code selection to select more than one needle for simultaneous operation. This means that the same design, in the same or different colors, will be repeated in different areas of the fabric during a single series of movements of the frames, the disposition of the areas of simultaneous repeat designs being a function of the spacial fixed separation between two or more selected needles of proper colors.

Mirror Patterns

Since patterns often take the form of mirror images across x and/or y center lines, it is obvious that the tape used to embroider one half or quadrant of a design can be used to perforate tapes for the other half or quadrants by mere reversals of x and y polarity codifications. Electric circuits are easily arranged to accomplish such reversals, contributing to the ease of preparation of repeated, reversed, and inverted design elements in control tapes.

Allover Patterns

By and large, embroideries are not allover patterns, but leave considerable areas of the base fabric exposed upon completion. In general, allover patterns therefore fall within the province of the weaving loom. However, weaving looms are not as versatile in some ways as embroidery machines, so that the electrically controlled, multiple-colored embroidery machine may find itself, in certain situations, in competition with the loom for producing allover patterns and even for solid textures of one color.

Solid or variegated colors may be embroidered economically row by row to achieve certain fabric textures not so readily obtainable by weaving, such as the chenilles. The simultaneous use of as many needles as practicable is indicated for such work. Manually thrown switches have been included in the experimental development for ganging selected needles for simultaneous release, use, and retraction, to embroider areas of solid or near solid colors.

Conclusions

It may be concluded that an initial design has been justified which has used a 5-unit 2-channel system for valid reasons beyond the obvious one of that system's availability. One of those reasons is that American communication companies are equipped[4] without changes in their circuits or apparatus to reproduce 5-unit control tapes at a distance and, simultaneously, at as many branch factories as may be desired.

From the results obtained by experimental operation of a prototype machine, it may be concluded that automation designers will find a valuable point of departure in the use of electromechanical units already familiar to telegraph engineers; and that the latter might profitably extend their normal interest in the transmission of intelligence signals over wires to comprehend the new uses of signals for the control of mechanisms, in the textile industry among others.

Rapid Measurement of Impedance and Admittance

B. SALZBERG
NONMEMBER AIEE

J. W. MARINI
NONMEMBER AIEE

Synopsis: A method is described for direct, rapid, and simultaneous measurement of the real and quadrature components of a driving-point or transfer impedance and admittance over a wide and continuous range of frequency. Basically, the method employs a mixer which derives its signal and local oscillator voltages from the voltage across and current through the unknown impedance respectively. With the unknown driven by a sinusoidal constant current, the mixer d-c output is linearly related to the unknown resistance. If the phase difference between the two derived voltages is altered by 90 degrees, the mixer d-c output is linearly related to the unknown reactance. To measure the components of an admittance, the unknown is driven by a sinusoidal constant voltage and the signal and local oscillator voltages are interchanged. Apparatus using this method for measurement of impedance and admittance in the frequency range of 50 kc to 5 megacycles (mc) has been built. With suitable modifications of detail, the method appears to be usable from acoustic to microwave frequencies.

THE increasing tempo of development and application of linear networks of all kinds has created a pressing need for impedance- and admittance-measuring apparatus with which results can be obtained rapidly and directly over wide and continuous ranges of frequency. A method for satisfying this need is described in the present paper; progress in this work has been reported in the past.[1,2] The method is applicable, in principle, from low frequencies to the very highest frequencies. It provides for rapid, direct, and simultaneous measurement of the real and quadrature components of a driving-point or transfer impedance and admittance over a wide and continuous range of frequency. Furthermore, it is well suited for visual presentation of the measurements and, hence, it is useful not only for the laboratory but for pedagogical purposes as well. Apparatus based on this method, designed for automatic or manual measurement of the two components of an impedance and admittance in the frequency range 50 kc to 5 mc, will be described and results of typical measurements will be presented. (During the course of our work we learned of a similar method and apparatus developed abroad.[3] Werthen and Nilsson apparently were unaware of the earlier work of Levy,[4] which seems to have anticipated much of their development. There are significant differences between the present paper and the work described in references 3 and 4.)

The steady-state currents in the meshes of a linear network resulting from the application of a voltage $V \sin pt$ to the driving-point terminals of the network are of the form $I \sin(pt+\theta)$. The relation between the amplitude of the applied sinusoidal voltage and the amplitude and phase of any particular mesh current is expressed by a quantity termed "impedance" or, by its inverse, "admittance." If the current under consideration is in the same mesh as the applied voltage, these terms are usually prefixed by the designation "driving-point"; if the current is in a mesh different from that in which the applied voltage appears, the prefix "transfer" is used. The generic quantities impedance and admittance are complex numbers whose values are determined by the angular frequency p and the parameters of the network. Although meaningful only for an applied sinusoidal force, these quantities are of fundamental importance because the response of a network to a nonsinusoidal force can be completely determined from a knowledge of their frequency dependence. These terms are defined as follows

$$\text{Admittance} = Y = G + jB = (I/V)\cos\theta + j(I/V)\sin\theta \quad (1)$$

$$\text{Impedance} = Z = R + jX = (V/I)\cos\phi + j(V/I)\sin\phi \quad (2)$$

where

G = conductance
j = quadrature operator
B = susceptance
V = amplitude of the voltage
I = amplitude of the current
θ = phase difference of current relative to voltage
R = resistance
X = reactance
$\phi = -\theta$ = phase difference of voltage relative to current

It is apparent from equation 1 that, if V is kept constant as the source frequency is varied, the conductance is directly proportional to the real component of the current, and the susceptance is directly proportional to the quadrature component of the current. The two components of an admittance can be determined, therefore, by maintaining V constant and measuring the quantities $I\cos\theta$ and $I\sin\theta$. Correspondingly, it is apparent from equation 2 that the two components of an impedance can be de-

Y., January 31–February 4, 1955. Manuscript submitted September 7, 1954; made available for printing January 6, 1955.

B. SALZBERG and J. W. MARINI are with the Naval Research Laboratory, Washington, D. C.

The authors wish to acknowledge the work of G. S. Kan who developed an earlier model of the apparatus. They thank also K. W. Bewig for his help on many phases of the development of the present model, and D. T. Phillips who designed the swept-frequency oscillator used with the apparatus.

termined by maintaining I constant as the source frequency is varied, and measuring the quantities $V \cos \phi$ and $V \sin \phi$.

The real component of the current or voltage can be measured directly by means of a wattmeter[3,4] which records $VI \cos \theta$. For example, if V is kept constant, the wattmeter reading is proportional to $I \cos \theta$. Alternatively, if I is kept constant, the wattmeter reading is proportional to $V \cos \theta$.

Similarly, the quadrature component of the current or voltage can be measured directly by means of a reactive-power meter. This is a wattmeter provided with a means for shifting the phase between applied voltage and current by 90 degrees, so that the device[3,4] records $VI \sin \theta$. Thus, if V is constant, the reading is proportional to $I \sin \theta$; if I is constant, the reading is proportional to $V \sin \theta$.

The device used in the present work for measuring directly the real and quadrature components of current or voltage is a mixer of the kind customarily used for frequency conversion in radio receivers. Such mixers are simpler and more practicable than a wattmeter, are readily available, and are operable over very wide frequency ranges, from low frequencies to the highest radio frequencies.

When a mixer is used for frequency conversion, it is supplied with a large local oscillator voltage $P \cos pt$ and a small signal voltage v of different frequency. The mixer output current contains a component, the intermediate-frequency output, whose amplitude is proportional to the amplitude of the signal voltage and whose frequency is the difference between the signal and local oscillator frequencies. In the present application, however, the voltages supplied to the mixer have the same frequency. In this case, the intermediate-frequency output reduces to a d-c term that is proportional to the product of the amplitude of the small signal voltage and the cosine of the phase difference between the two voltages supplied. This can be shown formally by expanding the mixer output current in a Fourier series in pt and a MacLaurin series in v.

$$
\begin{aligned}
i(P \cos pt, v) = {} & [A_0(P)+A_1(P) \cos pt + \\
& A_2(P) \cos 2pt + \ldots] + v[B_0(P) + \\
& B_1(P) \cos pt + B_2(P) \cos 2pt + \\
& \ldots] + v^2[C_0(P)+C_1(P) \cos pt + \\
& C_2(P) \cos 2pt + \ldots] + \ldots \qquad (3)
\end{aligned}
$$

This is a general expression for the output current of a nonlinear device driven by a cosinusoidal voltage $P \cos pt$ and a second applied voltage v. If, in particular, v equals $Q \cos (pt+\theta)$ and Q is small enough to permit powers of v higher than the first to be neglected, equation 3 shows that the d-c output of the mixer is $A_0(P)$ plus the term $[(1/2)B_1(P)] [Q \cos \theta]$. The latter term arises from the product $[B_1(P) \cos pt] [Q \cos (pt+\theta)]$. Since this product also produces the intermediate-frequency output of the device when v has a frequency different from p, $(1/2)B_1(P)$ can be identified as the conversion transconductance $g_c(P)$ of the device. The d-c output can therefore be written as

$$I = A_0(P) + g_c(P) Q \cos \theta \qquad (4)$$

where $A_0(P)$ is the d-c output when the mixer is driven by a reference voltage $P \cos pt$ alone, and $g_c(P) Q \cos \theta$ is the incremental d-c output when a small voltage $Q \cos (pt+\theta)$ of the same frequency is then applied. This incremental d-c output can be used to determine the real component of a current or voltage and can, therefore, also be used to measure conductance or resistance.

Altering the phase difference between the two alternating voltages by 90 degrees before applying them to the mixer input causes the incremental d-c output to be proportional to $Q \sin \theta$. This product can be used to determine the quadrature component of a current or voltage and, hence, the susceptance or reactance.

Method

MEASUREMENT OF ADMITTANCE

A sinusoidal voltage source of constant amplitude is connected to the driving-point terminals of the network under test. If the driving-point admittance is to be measured, a current-sampling resistance r is inserted in series with the source; if a transfer admittance is to be measured, the sampling resistance is inserted in series with the transfer mesh. To insure that the current is essentially undisturbed by the sampling resistance, the resistance is made very small relative to the impedance of the circuit in which it is inserted. The reference voltage $P \cos pt$ across the driving-point terminals is applied to the input of a mixer; the resultant d-c component of the mixer output current has some constant value. The smaller voltage drop $rI \cos (pt+\theta)$ across the sampling resistance is proportional to the current, driving-point, or transfer as the case may be. This voltage is also applied to the mixer input, with the result that the d-c component of the mixer output current is changed in accordance with equation 4 from its constant value $A_0(P)$ by an amount $g_c(P) rI \cos \theta$. The change, as will be seen from equation 1, is proportional to the conductance being measured. The recording device which indicates the change in mixer d-c output current can be calibrated directly in units of conductance by substituting an admittance of known conductance for the network under test.

To determine the susceptive component of the admittance being measured, the phase difference between the two alternating voltages is shifted by 90 degrees before the voltages are applied to the mixer input. The resultant change in the d-c component of the mixer output current is then $g_c(P) rI \sin \theta$. This, as will be recognized from equation 1, is proportional to the susceptance being measured. If the same calibration as before is used, the recorder will indicate susceptance directly. Alternatively, the recorder can be calibrated by substituting an admittance of known susceptance for the network being measured.

MEASUREMENT OF IMPEDANCE

To measure the components of an impedance, the method is modified as follows: the constant-voltage source is replaced by a constant-current source; the latter is connected in series with a sampling resistance to the driving-point terminals of the network to be tested. The voltage $rI \cos pt$ across the sampling resistance is in phase with and proportional to the applied current; it is the first of the two alternating voltages which are applied to the input of a mixer. The second voltage is obtained from the input terminals of the network if the driving-point impedance is to be measured, or from the output terminals of the network if the transfer impedance is to be measured. In either case, this voltage has the form $V \cos (pt+\phi)$ so that the resultant change in the d-c component of mixer output current is $g_c V \cos \phi$. As will be seen from equation 2, this change is proportional to the resistance being measured. The recorder which indicates the change in mixer d-c output current can be calibrated directly in units of resistance by substituting an impedance of known resistance for the network under test. The reactive component of the impedance is determined in the same way, except that the phase difference between the two alternating voltages is shifted by 90 degrees before they are applied to the mixer input.

SWEPT-FREQUENCY MEASUREMENTS

This method of measurement not only provides direct readings of driving-point or transfer admittance and impedance components but may also serve for automatic and simultaneous presentation of the values of real and quadrature components. If the frequency of the constant-amplitude source is varied continuously over a band, at a relatively slow rate, the recorder will indicate the measured value of a component as a continuous function of frequency. Furthermore, if two mixers are used simultaneously, as previously described, readings of the values of both components as continuous functions of the frequency are made available. These readings of each of the components can be displayed separately as functions of the frequency or, if desired, they can be presented together in the form of a polar graph or circle diagram plot.

EVALUATION OF ERRORS

It will be noted that the method requires a source of constant amplitude—constant voltage if an admittance is to be measured, or constant current if an impedance is to be measured. This requirement demands the use of some form of automatic regulation or compensation. But even with a well-regulated source, there is invariably some departure from constancy of amplitude. As a result, errors in measurement can occur. In principle, if the output of the electronic device used to make the measurement were uninfluenced by variations in the amplitude of the reference voltage, the error would be equal to the fractional deviation from constancy of the source amplitude. Normally, the source amplitude could easily be maintained sufficiently constant to keep this error well within the usual engineering tolerances. In practice, however, the desired output of available mixers depends upon the amplitudes of both input voltages. This results in the introduction of two additional kinds of error, both of which are caused by variations in the amplitude of the reference voltage.

Referring to equation 4, if the amplitude P of the reference voltage applied to the mixer input varies, the output d-c component or reference output $A_0(P)$ also varies. The deviation from constancy of reference output constitutes one kind of error—the reference error. In addition, the conversion transconductance $g_c(P)$ is no longer constant. This is the source of the other kind of error, denoted as slope error.

In most cases, $g_c(P)$ varies slowly with changes in P, so that the slope error is less than the fractional deviation of P and is not very important. Reference error, however, can be serious. The value of Q in equation 4 must be kept small to insure linearity of operation. Consequently, the term $g_c(P)\ Q \cos\theta$, which is the output to be measured, may be only a small percentage of $A_0(P)$. Accordingly, a small percentage change in the latter term can produce a large error. In fact, under some circumstances, the reference error can be so large that the method of measurement becomes inoperative.

Reference error can arise from another source. In practice, the reference input voltage, represented heretofore as $P \cos pt$, also may contain harmonics of the fundamental angular frequency. The reference output $A_0(P)$ depends not only on the amplitude P of the fundamental but also on the presence of such harmonics. If the wave form of the reference input changes, as it might, e.g., in a swept-frequency measurement, reference error from this source occurs.

METHOD FOR ELIMINATION OF REFERENCE ERROR

While reference error can be reduced by careful choice of the operating conditions of the mixer to minimize the dependence of $A_0(P)$ on P or by use of a differential arrangement of matched tubes to balance out changes in $A_0(P)$, the error from this term can be eliminated altogether as follows: the amplitude Q of the smaller of the two alternating voltages derived from the network under test is modulated at some convenient audio-frequency before the voltage is applied to the mixer. In the case of sinusoidal modulation of Q at an angular audio-frequency a the mixer output of equation 4 becomes

$$\begin{aligned} I &= A_0(P)+g_c(P)Q(1+m\sin at)\cos\theta \\ &= A_0(P)+g_c(P)Q\cos\theta+mg_c(P)Q\cos\theta\sin at \qquad (5) \end{aligned}$$

The last term on the right of equation 5 is an audio-frequency term whose amplitude is proportional to the incremental d-c output in equation 4. This amplitude, therefore, can be used instead of the latter output to measure the components of an admittance or impedance.

If a band-pass filter centered at the modulating frequency is used as the output circuit of the mixer, the output voltage is made unresponsive to all other components of the mixer current, eliminating thereby the large d-c reference output $A_0(P)$ and the reference error associated with it. A linear voltmeter used to measure the amplitude of the output voltage from the band-pass filter, however, would provide only a positive output. Consequently, to determine the signs of the components as well as their magnitudes, phase-sensitive demodulation[5] must be used.

MEASUREMENT OF THE QUADRATURE COMPONENT

As stated previously, measurement of the quadrature component requires a 90-degree alteration of the phase difference between the two alternating voltages which are derived from the network under test and applied to the mixer. If measurements are to be made manually at a single frequency, this requirement can be met quite simply, e.g., by processing the reference voltage through an resistance-capacitance circuit. However, if measurements are to be conducted automatically over a wide frequency range, the situation becomes more involved. Not only must a 90-degree phase shift be obtained throughout the entire frequency range but the amplitude of the reference voltage must also be maintained constant to within the limits imposed by the maximum allowable reference and slope error.

One method for obtaining the 90-degree phase shift is to heterodyne the two voltage samples obtained from the network under test to a fixed intermediate frequency before applying them to the mixer. The required phase shifting is then easily accomplished at the intermediate frequency. This method can be used not only at acoustic and video frequencies but also, with appropriate changes in the means for obtaining voltage samples, at microwave frequencies as well. The method, however, requires auxiliary converters and a tracking heterodyne source whose frequency differs from that of the main source by the intermediate frequency.[3,4]

In principle, the 90-degree phase-shifting requirement can be circumvented by using a source which provides two constant-amplitude outputs, the phase difference between these being 90 degrees at all frequencies.[6] One of the two outputs is used to drive the network under test and to provide a constant-amplitude reference voltage for measuring the real component. The other output is used as a 90-degree phase-shifted reference voltage of constant amplitude for measuring the quadrature component. However, if admittances of high values are to be measured, the driving output-voltage source should have a very low internal impedance so that the 90-degree phase difference is maintained between the voltage applied to the network and that supplied by the auxiliary output. (The latter requirement does not apply to the measurement of impedance.)

Fig. 1. Impedance-measuring apparatus, block diagram

A third method for shifting the relative phase of the two voltages by 90 degrees is the employment of a wide-band phase-shifting network.[7] A fourth method, employed in the apparatus described in the following, makes use of a simple resistance-capacitance circuit which provides a 90-degree phase shift together with an automatic volume control (avc) system which maintains the output constant as the frequency is varied.

Apparatus

Laboratory apparatus for automatic or manual measurement of the real and quadrature components of a driving-point or transfer impedance and admittance has been developed for the video-frequency range of 50 kc to 5 mc. The available impedance ranges are from 0 to 100 and 0 to 1,000 ohms. The available admittance ranges are from 0 to 100, 0 to 1,000, and 0 to 10,000 micromhos. Automatic measurements are made by sweeping the source frequency through convenient portions of the video range at a rate of 1 cycle per second or less, depending on the characteristics of the network being measured. The real and quadrature components are measured simultaneously and the results are displayed on a cathode-ray oscilloscope.

The apparatus used for measuring the driving-point impedance is shown schematically in Fig. 1. A variable video-frequency source of sinusoidal voltage, the amplitude of which is automatically controlled, is connected in series with a resistor r to the unknown impedance Z. The value of r is 100 times greater than the maximum value of the impedance range used; the current I through Z, therefore, is limited by r and is essentially independent of Z. The small voltage IZ developed across Z is used as a signal voltage. The relatively large source voltage V, essentially a replica of the voltage rI developed across r, is used as a reference voltage.

The signal voltage is amplified by a single-state video amplifier A_1 and then amplitude-modulated at 1 kc in grid-circuit modulator AM, where a modulating voltage of constant amplitude is supplied from audio source S. To suppress undesired audio-frequency modulation products, a high-pass filter is used for the output circuit of the modulator. The amplitude-modulated signal voltage is applied to two identical single-stage video amplifiers A_5 and A_6 followed by like parabolic-law mixers M_1 and M_2.

The reference voltage is applied through a resistance-capacitance video circuit N

1, 74

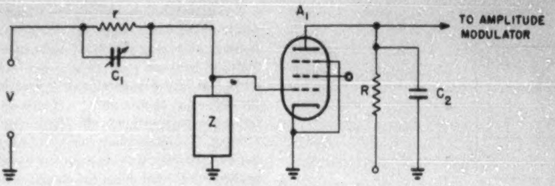

Fig. 2. Impedance-sampling circuit

to two identical single-stage video amplifiers A_3 and A_4. The output of A_3 is connected to an avc which controls the video source to maintain constant the amplitude of the reference voltage at the outputs of A_3 and A_4. The output of A_4 is connected to the input of M_1 through a plate load circuit common to both A_4 and A_5. Mixer M_1 is thus supplied with a small amplitude-modulated video signal voltage and a relatively large video reference voltage of constant amplitude.

The reference voltage is also applied to a variable-gain single-stage video amplifier A_2 which is followed by a 90-degree phase shifter P and a single-stage video amplifier A_7, whose output circuit is common to A_6. The reference voltage is applied through this common circuit to the input of M_2, and also to an avc which controls the variable-gain stage so as to maintain constant the amplitude of the phase-shifted reference voltage at the mixer input. Mixer M_2 is thus supplied with a small amplitude-modulated video signal voltage and a relatively large 90-degree phase-shifted video reference voltage of constant amplitude.

It is essential to preserve the relative phase between signal voltage IZ and reference voltage V; for this reason, the phase characteristics of the signal-voltage channel A_1–AM–A_6 and reference channel N–A_4 are matched over the operating video-frequency range. Because the avc which controls the video source is operated from the output of A_3 instead of directly from the source output, the response characteristics of these two channels need not be flat; they need merely be identical. Likewise, the phase shifts through channels A_1–AM–A_6 and A_2–P–A_7 are adjusted to differ by 90 degrees over the operating video-frequency range.

The signs of the components as well as their magnitudes are obtained by adding a constant audio-reference voltage from source S to the audio-frequency output of each of the mixers. The resultant voltages are applied to bandpass amplifiers BPA. These amplifiers have a flat passband of ±300 cycles per second about the modulating frequency. This band is wide enough, for the sweep rate used, to amplify faithfully the varying modulating frequency components of the mixer outputs, and yet narrow enough to suppress all undesired mixer output components. The d-c output of the demodulators which follow the BPA units are measures, with respect to both magnitude and sign, of the real and quadrature components of the unknown impedance. These direct voltages are applied to a standard 5-inch cathode-ray oscillograph.

Calibration of the apparatus is effected by substituting a standard resistance for the unknown impedance and adjusting the oscillograph gain so that maximum deflection in each channel corresponds to full scale value of the particular impedance range used. A standard deflection from the output of the channel which measures the quadrature component is obtained by switching out the phase shifter P during the calibrating process.

The circuit used to obtain a signal voltage from the unknown impedance is shown in Fig. 2. The resistor r is made large with respect to Z, as stated previously, to provice Z with a constant current. At the high-frequency end of the operating range however, both the distributed shunt capacitance across r and the total output distributed capacitance C_2 of the pentode amplifier produce unwanted phase shifts. Consequently, a trimmer capacitor is added across r and adjusted so that RC_2 equals rC_1, where C_1 is the total shunt capacitance across r. With this adjustment the phase shifts cancel and the pentode output voltage is proportional to Z, provided that the latter is small compared to the reactance of C_1 and the input capacitance of A_1.

Details of the 90-degree phase-shifter stage P are shown in Fig. 3(A). The product RC is made as large as is practicable so that the phase shift is nearly 90 degrees. Then, to obtain a phase difference of exactly 90 degrees between channel A_2P–A_7 and channel A_1–AM–A_6, the complementary circuit shown in Fig. 3(B) is used in the grid circuit of amplifier A_6. The resistance-capacitance arrangement used as the output circuit for stage P causes the output voltage to vary inversely with frequency; to provide the necessary constant output voltage, and avc arrangement shown in Fig. 1 is used.

Both diode mixers and parabolic-law pentode mixers have been used successfully in the present apparatus. For adequate linearity with such mixers, unless a differential arrangement is employed, the ratio of large reference voltage to small signal must be of the order of 100 to 1. Because of the consequent relatively large reference error, these mixers were used only in conjunction with the auxiliary signal modulation system shown in Fig. 1. Pentagrid converters alone, however, yielded fairly satisfactory results in an early model of the apparatus in which auxiliary modulation of the signal voltage was not employed. With such multigrid tubes, the output was linear for ratios of large reference voltage to small signal voltage as low as 10 to 1, provided

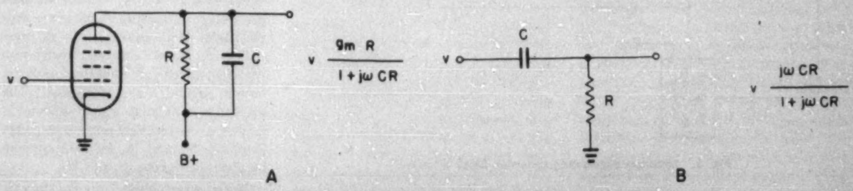

Fig. 3. (A)—Ninety-degree phase-shifting circuit. (B)—Compensating network

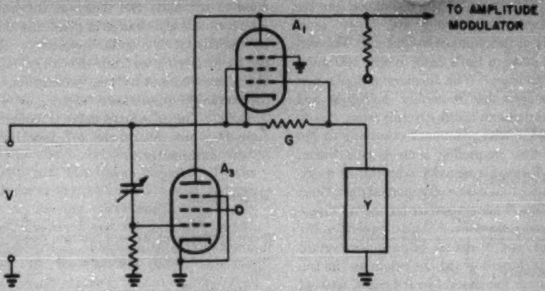

Fig. 4. Admittance-sampling circuit

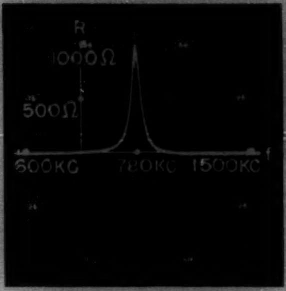

Fig. 6. Resistance versus frequency for a parallel resonant circuit

proper polarizing voltages were chosen. A large screen-grid resistor was used to minimize reference error resulting from changes in amplitude of the large reference voltage.

The video source is a heterodyne-type oscillator consisting of an electronically swept phase-shift oscillator,[8] variable from 20.050 to 25 mc, whose output is mixed in a frequency converter with a 20-mc signal from a fixed oscillator to produce a 50-kc to 5-mc output. The amplitude of the output is controlled by varying the gain of a tuned buffer amplifier between the fixed oscillator and the frequency converter.

To measure the components of a transfer impedance instead of a driving-point impedance, the video source is connected in series with resistor r to the driving-point terminals, as shown in Fig. 1, but the small signal voltage is now derived from the transfer mesh. The results of measurement thus represent real and quadrature components of the voltage in the transfer mesh, referred to the driving-point current. By definition, this is the transfer impedance.

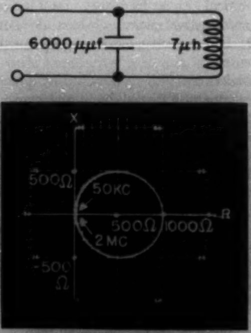

Fig. 5. Reactance versus resistance for a parallel resonant circuit

It is usually desirable to be able to ground one terminal of both the video source and an unknown impedance or admittance being measured. This can be done, when measuring an impedance, by deriving the reference voltage from the source, as shown in Fig. 1, rather than from the voltage developed across the current-limiting resistor r. When the driving-point admittance is measured, however, it is necessary to maintain a reference voltage of constant amplitude at the driving-point terminals and to derive the small signal voltage from a series-connected current-sampling resistance. Under these conditions, the sampling resistor must be floated above ground. Details of the arrangement actually used for measurement of an unknown driving-point admittance Y are shown in Fig. 4. The conductance G of the sampling resistor is large compared with Y; in practice, G is 100 times greater than the maximum value of the admittance range used so that the source voltage is essentially entirely across Y. A floating pentode amplifier A_1 is used to sample the voltage drop across G. A second pentode is used to balance out the effect of stray capacitance across Y and of screen-to-plate capacitance of A_1. If, in practice, G cannot be obtained as a pure conductance, the error otherwise introduced by the susceptive component can be eliminated by replacing the plate load resistor of the pentodes by a suitable compensating network.

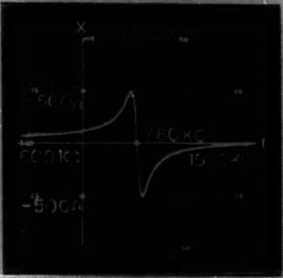

Fig. 7. Reactance versus frequency for a parallel resonant circuit

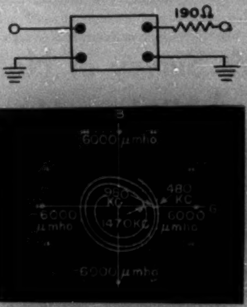

Fig. 8. Transfer susceptance versus transfer conductance for a delay line

To measure the components of a transfer admittance instead of a driving-point admittance, the video source is connected directly to the driving-point terminals. The voltage across these terminals is used as the large reference voltage, and the small signal voltage is derived across a series sampling resistance inserted in the transfer mesh.

Typical Results

Typical results obtained with the laboratory apparatus described in the foregoing indicate that the principles employed are sound and that design of useful apparatus of this type is feasible. The error of the apparatus in any measurement depended on the impedance and frequency ranges involved. Spot checks indicated that this error was usually within the range of linearity of the oscillograph used as a recorder, which was about 5 per cent. In some cases this error was exceeded, however, especially at low or high frequencies where the video channels failed to line up identically. Typical results obtained with the apparatus are shown in Figs. 5 through 8. These photographs are time exposures taken with a Polaroid-Land camera.

Figs. 5 through 7 resulted from the measurement of a parallel resonant circuit consisting of a 6,000-micromicrofarad capacitor in shunt with a 7-microhenry inductor which has a Q of 30 at the resonant frequency of the circuit. Fig. 5 shows a polar plot of the input impedance of the circuit over the range from 50 to 2,000 kc. The resistance and reactance can be read from the horizontal and vertical axes respectively. The scale is 100 ohms per division so that the maximum value of the equivalent series resistance is seen to be 1,000 ohms. This agrees with the value calculated by multiplying the Q, measured on a Q meter, by the reactance of one of the components at resonance $Q(L/C)^{1/2}=30\ (7\times10^{-6}/0.006\times10^{-6})^{1/2}=1{,}000$ ohms.

In Figs. 6 and 7 the resistance and the reactance respectively are shown separately as functions of frequency. The vertical scale in both cases is still 100 ohms per division. The horizontal scale now represents the frequency, however, and the range exhibited extends from 600 to 1,500 kc, with resonance occurring at 780 kc. The frequency scale is not linear. Fig. 8 shows a transfer admittance measurement taken on a commercial delay line. The line is advertised as having a "Gaussian response curve." Consequently, the tip of the transfer admittance vector spirals down toward the origin as the frequency is increased toward cutoff instead of making a circle about the origin as is the case for lines with the conventional flat response. The scale is 600 micromhos per division.

The frequency markers and the origin in Fig. 8 were inserted photographically by a method described by Levy.[4] The curve for the delay line was photographed with the video-frequency source sweeping automatically over the desired range. The automatic sweeping mechanism was turned off and the source frequency was adjusted by means of a calibrated dial to 480, 980, and 1,470 kc successively, an additional exposure of the photographic plate being made at each frequency. Finally the network was switched out and an exposure was made to locate the origin. The frequency markers can be used to calculate the delay of the line, which equals the change in phase divided by the change in angular frequency. As the frequency varies from 480 to 1,470 kc, the phase changes by two revolutions of the transfer admittance vector, or 4π radians. The calculated delay is 2 microseconds, which is also the delay specified by the manufacturer.

A Survey of Noncontacting Vibration Pickups Using Electric Fields

HOWARD F. CLARKE
NONMEMBER AIEE

THE growing importance of vibration requirements in the field of component testing has created an increasing need for means of measuring the magnitude of the vibrating forces and displacements to which components are subjected. In general, quantities should be measured; acceleration, velocity, and displacement. While it is always advantageous to measure directly the quantity to be known, it is quite easy to convert data from one quantity to the other when the frequency and wave form are known.

There is a large variety of methods, electrical, mechanical and optical, which may be used to measure vibrations; however, by far the most common method is to convert the vibration into electric signals, and then to measure the electric signal. If this procedure is followed, the main problem of the measurement lies in the transducer making the conversion.

There are a number of devices on the market for the conversion of vibrations to electric signals, which might be divided into three classes, according to whether displacement, velocity, or acceleration is the quantity intended to be measured. Displacement and velocity can be converted directly to electric quantities, and several transducers are available for this purpose. Acceleration is usually mechanically converted to displacement, using a spring-mass system operated well below resonance, and the displacement is then applied to a displacement transducer. It should be noted that this places theoretical upper-frequency limitations on acceleration pickups which do not hold for velocity and displacement pickups.

Acceleration may be obtained by direct measurement of displacement and knowledge of the wave form and frequency. There is a disadvantage to the use of displacement-measuring devices if acceleration constant over a considerable frequency range. Nevertheless, the freedom from the disadvantages of resonating systems is of sufficient importance

Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing January 21, 1955.

Howard F. Clarke is with the Boeing Airplane Company, Seattle, Wash.

to make displacement-measuring systems of considerable use in vibration measurement. In this paper a class of displacement-measuring devices is described.

In the systems to be discussed, no mechanical connection is made to the vibrating body, the vibrating displacement being sensed by its effect on an electric field between the vibration pickup and the object shaken. In the transducer system shown in Fig. 1, there are no moving parts except the object being shaken, thereby eliminating pickup resonances or modes of vibration which arise to trouble the user. Another distinct advantage is that the pickup does not mechanically load the vibrating body. The system may be arranged to have negligible side-sensitivity and almost no practical limit to its frequency response from zero frequency up. This means that these devices are especially well adapted for use as transfer devices between static and dynamic displacements as they may be calibrated statically.

Perhaps the greatest disadvantage to electric field systems is the fact that their sensing field cannot be confined to a small area without also confining their linear range. A second disadvantage is that the vibrating surface which they see must usually have some known geometry, such as a flat sheet. Also, the nature of the material of the vibrating surface seen is critical, the systems being chiefly set up to see surfaces of nonferromagnetic materials of high conductivity. Their response to a surface of geometry and material other than the foregoing will be described as each method is taken in turn. The three methods of using electric fields to pick up vibrations will be discussed in detail in the following.

Capacitance-Type Vibration Systems

Historically, the first field-type pickup was the capacitor microphone. As this is quite familiar to everyone, it will not be discussed further except to consider it as a possible vibration pickup for the purpose of comparison with some of the systems to be discussed.

The chief disadvantage of capacitive vibration pickups would appear to be the difficulty in obtaining sensitivity and linearity with small probe size. In the capacitance-type pickup, the capacitance of the sensing element itself is often no greater than the leads connecting it to the following circuit. Since the capacitance of these leads is in parallel with the capacitance of the sensing element, the effective percentage change in the sensing-element capacitance, as seen by the circuit, becomes smaller as the leads grow larger.

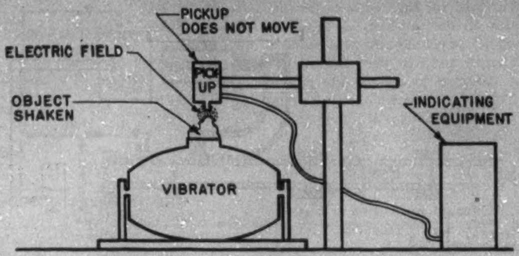

Fig. 1. Vibration setup using field pickup

The frequency response of the ordinary microphone will not extend down to direct current because of the use of d-c excitation through a shunt resistor, and, therefore, such a device will not serve as a transfer between static and vibratory displacements. For static to dynamic displacements, a carrier system must be used. The capacitance probe could be used to determine the frequency of a frequency-modulated system but, here again, problems of linearity may be encountered. For stability and noise level the capacitance probe appears comparable with other systems and could not be disturbed by ferromagnetic material in the target.

It is quite possible that methods will be found of overcoming or minimizing the shortcomings of such systems so that they may be considered as comparable in possibilities with the other electric field systems to be described. However, the foregoing reasons have tended to channel development away from capacitance-type pickups at Boeing Airplane Company.

Microwave Systems

These systems use assemblies of standard-type plumbing components in the region of 10,000 megacycles to pick up vibration by the changes in the power which is reflected back into a radiating system by the vibrating surface when it is placed close to the source of radiation. The aforementioned frequency is by no means suggested as optimum, but is rather a convenient high frequency for which a wide variety of components are commonly available.

Microwave systems are somewhat related to the capacitance-type pickup in which a carrier frequency is used. However, it has been pointed out that in a capacitance-type pickup, capacitance changes in a small sensing element tend to be lost in lead capacitance. With high frequencies, a change in even a very small capacitance appears as an appreciable susceptance change and, if this is applied at the termination of a transmission line, the resulting change in reflection coefficient of the termination, as seen at the input terminals of the line, is not appreciably diminished by increasing the length of the line. Thus, systems using very high frequencies have two advantages; a small change of geometry shows a comparatively large change in reactance or susceptance, and this change may be propagated down a transmission line without serious loss.

Of the three systems worked out by the author, two are sufficiently useful to warrant a description here.[1] In Fig. 2, a microwave oscillator 2 feeds energy to a wave guide 3 through a dissipative pad 4 which has as its purpose the minimization of disturbances in the oscillator out from

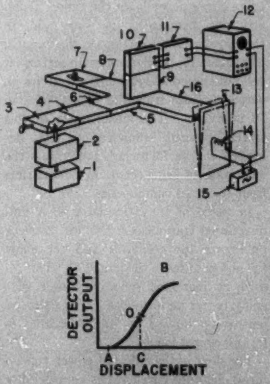

Fig. 2. Magic T field pickup

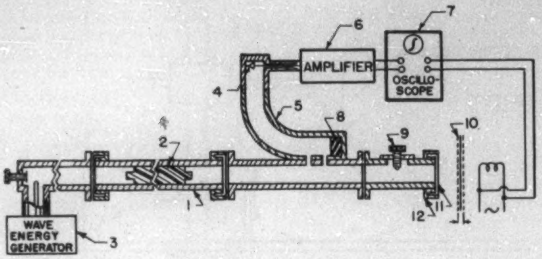

Fig. 3. **Directional coupler field pickup**

variations in the impedance of the load. From the dissipative pad, the power enters a branched guide of the type known as the magic T, 5. On one horizontal arm 8 of the magic T is placed an impedance, arbitrarily variable in phase and magnitude 7. The top branch of the T, 9, feeds a crystal detector 10. The opposite horizontal branch of the T is extended into a wave guide 16 which terminates in an open end within a few millimeters of the vibrating surface 13. The vibrations of this surface are in a line parallel to the center line of the wave guide.

In use, the impedance 7 is adjusted so that the variation of the impedance reflected from the open end of the wave guide centers about a point somewhat removed from the null point of the system, being chosen in such a manner that the output of the detector is a linear function of the distance of the wave guide to the reflecting sheet, over as long a range of distance as possible. This linear section of the detector-output-versus-target-distance curve depends on the target geometry, the distance of the wave guide to the target, and the settings of the variable impedance 7. Under optimum settings it will not exceed about 2 millimeters for an output voltage from the crystal of 8 to 10 millivolts. The linear range of this system is small compared to that described in the following, but it has the advantage of being set up in a short time from standard components.

In place of the attenuator 4, a unidirectional transmission line will prevent pulling of the oscillator and yet allow full power to reach the magic T. This results in increased sensitivity and generally better performance. The figure of sensitivity quoted in the foregoing is for this arrangement.

The slope of the reflected-power-versus-target-distance curve varies considerably with the materials of the target but is usable for a wide variety of materials including nonconductors, provided their characteristics are such that a reasonable percentage of the power incident upon them is reflected at the surface.

The system shown in Fig. 3 differs from the preceding one in the nature of the pickup mechanism. The heart of the device, the 10-decibel directional coupler, is not as commonly available as the magic T of the preceding method and, thus, this system is not as easily set up. However, the linear range of this system is about 1/4 inch long, thus considerably exceeding that of the preceding system.

In Fig. 3, a microwave generator 3 (usually a *723 A/B* klystron) couples power into a wave guide, after which it is passed into an attenuator 2 (the writer used about 3 decibels), the purpose of which is to prevent pulling of the oscillator by impedance variations of the load. The unidirectional transmission line referred to previously would probably be an improvement here but, since the 10-decibel coupler is not now conveniently available, it has not been tried. From the attenuator, the power passes down a directional coupler 5, which is set to couple power from reflections. From the directional coupler, the power enters a single screw tuner 9, the function of which is to reflect a portion of the power back to the directional coupler in such a manner as to control the linearity of the device. From the screw tuner, the power passes out through a choke fitting 12, is reflected from the vibrating surface 10, reenters the wave guide, passes back to the directional coupler, combines with the power reflected from the screw tuner, and is detected in the directional coupler output 4.

The action of the system can be traced as follows. Neglect for the moment the screw tuner and the choke fitting on the end of the wave guide facing the vibrating surface. If the end of the wave guide is assumed to be a spherical radiator and the vibrating surface to be a mirror, then, as the mirror recedes from the end of the wave guide, the power reflected back into it will drop off as the square of the distance. As the target further recedes from the end of the wave guide, the power reflected from the target is alternately reinforced by the reflections from the unmatched termination of the wave guide and is cancelled by them. This is shown in Fig. 4, curve *A*.

It is seen that a point of inflection in the curve does not occur until the target is quite far away from the end of the wave guide, thus giving only small sections of the curve which may be considered linear. Now consider a choke flange place on the terminating end of the wave guide. If the choke acts here as it does in the standard line connections, 100-per-cent reflection, or nearly so, should be expected until the target has receded an appreciable distance from the wave guide. This gives the curve *B* in Fig. 4. Here it is seen that a point of inflection occurs in the part of the curve where there is appreciable power being reflected back into the wave guide. However, the linear region is still not as long as desirable. To lengthen the linear region, a screw tuner is inserted in the line to introduce a reflection into the wave guide of such phase as to cancel partially the reflections at the lower part of the curve. The only effect of this reflection on the upper part of the curve, where the reflection is approaching 100 per cent, would be to change the phase. But, as the directional coupler detects only the reflected power without regard to its phase, there

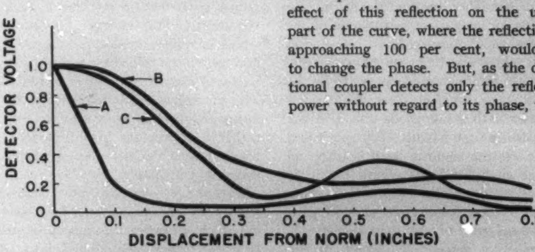

Fig. 4. **Displacement versus output curves, directional and coupler pickup**

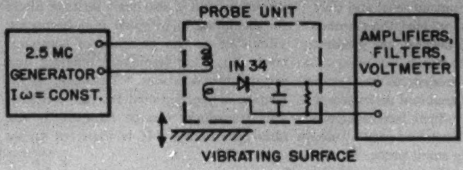

Fig. 5. Mutual inductance field pickup

is very little change in this region. The result is a staisfactorily long linear region, shown in curve *C*, Fig. 4.

The linear range and stability of the directional-coupler system is considerably better than the magic T system previously described. The sensitivity at the detector is approximately 5 millivolts per mil of displacement. To use this device for static calibration against dynamic displacement, either the amplifiers which follow the detector (11, Fig. 2; 6, Fig. 3) must be of the d-c variety or the ouput of the detector must be chopped. The writer, using fairly crude methods, was able to check optical methods of measuring vibrations to 5 per cent or better without difficulty.

Both systems described in this section require a target area at least 1 inch square of flat conducting material. A probe of very small dimensions capable of looking at very small target areas seems possible by going to coaxial lines and tapering them to small dimensions; however, this has not been investigated. In fact, the number of possible probe geometries appears quite large. But it must be remembered that, in almost all cases, the linear range of the probe will always be appreciably less than the probe dimensions. This is true of any electric field pickup, to the best knowledge of the writer.

The sensitivity of a microwave system varies with the configuration used, being greatest in the directional-coupler variety, and is directly proportional to the power fed into the probe by the oscillator. Thus, the use of continuous-wave magnetrons, or sources of greater power than is produced in the *723 A/B* klystron, is promising for this purpose.

The linearity of microwave systems depends on the particular system used, that of the directional coupler type being adjustable within the limits of the linear portion of the curve by the screw tuner. The stability of and freedom from noise and extraneous signals of the system depend almost entirely on the oscillator. The systems are not, however, very compact, and, in spite of the folding of the line and its components, tend toward bulkiness and weight.

Mutual Inductance Systems

National Bureau of Standards System

The first system to be discussed here is that developed by Yates, Davidson and Greenough.[2,3] of the Bureau of Standards. The basic idea is shown in Fig. 5. The mutual inductance of two coils is varied by the presence of a conducting plate, the mutual inductance decreasing as the conducting plate approaches the unit. If now the first coil is supplied with power in such a way that the product of frequency and current is held constant, then the voltage from the second coil depends only on the position of the conducting plate. By suitable arrangement of the two coils and the circuitry supplying them, the target distance versus coil output can be made a linear curve.

At the frequency used here (in the neighborhood of 2 megacycles), the output voltage from the secondary coil would be seriously attenuated by cable capacitance and, therefore, it is desirable to place the detector close to the coil and send only the rectified output back through the probe cable. This is done in the National Bureau of Standards device by the use of a germanium diode mounted in the barrel of the pickup probe.

The geometry and arrangement of the two coils can be varied considerably. However, since it is best to have a target area as large as the largest coil, the size of the coils should be as small as the requirements of the linear region will permit. It should not be expected that the linear region will exceed in length a small part of the coil diameter; a figure of 7 per cent has been suggested. It would seem desirable to have one coil smaller than the other, on a basis of experience, and the separation along their axis may vary from zero to a distance equal to about half the diameter of the larger.

It has been stated that the product of frequency and current must be held constant. To do this, the primary of another pair of coils is inserted for monitoring purposes in series with the lead supplying the primary of the pickup coil with power. The output voltage of the secondary of their pair of coils is rectified, filtered, amplified, and fed back to the screen of the oscillator tube in such a manner as to raise the screen voltage of the oscillator tube, and thus its output, should the product of frequency and current start to decrease.

For system is calibrated statically as follows. A zero position at the start of the linear portion of the curve is selected and the probe is placed in this position. The steady d-c output caused by this position is bucked out by suitable circuitry. The probe is now displaced a known amount, thus giving a net output equal to the change caused by its shift in position. This new d-c output of the probe is chopped, and the resultant square wave is fed to an amplifier, and to a voltmeter set to read peak-to-peak voltages. For further details see reference 3.

Boeing Modification of the National Bureau of Standards System

A frequency-modulated system has been developed which eliminates the effect of cable capacitance between the probe and detector. It is essentially an extensive modification of the National Bureau of Standard mutual inductance pickup and uses the variation of the mutual inductance of the probe to vary the frequency of an oscillator. The oscillator frequency is then fed into a discriminator. The chief advantages of the frequency-modulated system appear to be smaller possible probe sizes, the use of longer cables, and increased stability and sensitivity. At this time, however, the system is still under development and, therefore, there are few experimental data on it. It is being developed as a displacement pickup for reading static displacement; however, there seems to be no apparent difficulty in incorporating the frequency-modulated features into the vibration standard of the National Bureau of Standards.

Summary

Capacitive systems are widespread and varied; they are among the oldest of the methods of picking up vibration. They suffer most from difficulties caused by the capacitance of the leads attached to the sensing element; also there are difficulties inherent in producing a linear system. They are less particular about the conductivity of the material looked at in the vibrating surface, and ferromagnetic materials would cause no trouble with them, but their usefulness on nonconductors seems limited. They require probes of appreciable size. Their output is usually low level.

Microwave systems have as great a possible variety as capacitive systems, and have the advantage that a small geometry change at very high frequencies can effect a large reactance change. They are usable on nonconductors which will give appreciable reflections from their surfaces, and they also will work on magnetic material.

The probe size required at the present time is comparable to other systems, but there seems a possibility that very small probes might be made with a larger linear region, in relationship to probe size, than with the other systems discussed. One variety may be made with standard components available in any radar laboratory. Their chief drawback is bulkiness and low output level and they are probably less stable than other systems, although there is, as present, a lack of data on this point.

Mutual inductance systems are probably the most developed and perfected of any of the methods. They have been engineered for convenience and ease of use, and have moderately small probes on the end of cables to the indicating equipment thus eliminating bulky pickups being placed near the vibrating object. They give high output voltages for small displacements. They cannot be used on nonconducting materials. The National Bureau of Standards system has an established calibrating procedure, permitting direct reading in inches, end to end of the vibration, and it also has a series of filters for examination of small high-frequency vibrations in the presence of comparatively large low-frequency building and apparatus vibrations. The new modification of the National Bureau of Standards transducer can be handled by the same procedures. It is expected to be quite stable.

Effects of Transverse Compressional Stress on Magnetic Laminations

R. E. FISCHELL
ASSOCIATE MEMBER AIEE

Synopsis: Toroidal, laminated cores of several important magnetic materials were tested for their magnetic properties at compressional stresses ranging from 0 to 500 pounds per square inch (psi). The compressional stress was applied in a direction perpendicular to the plane of the laminations and perpendicular to the direction of the magnetic field. The materials tested were 3.5 and 6.4-per-cent silicon-iron, 81 and 90-per-cent nickel-iron, and both hydrogen- and air-annealed samples of *AEM 4750*, 12 Alfenol, and 16 Alfenol. Tests were run at frequencies of zero, 60, and 400 cycles per second (cps). Under the action of an increasing compressional stress, each of the materials having nonzero magnetostriction exhibited a decrease in maximum permeability and remanence, an increase in coercive force, and a maximum flux density which remained virtually unchanged. The a-c magnetization curve was shifted downward, and the a-c hysteresis loops became less rectangular as the compressional stress was increased. Except at very low fields, materials having zero magnetostriction were unaffected magnetically by the transverse compressional stress. The experimental results indicate that magnetic effects of transverse compressional stress are dependent on the magnitude and independent of the sign of the magnetostriction. The results of this paper can be applied in choosing a magnetic material for a particular application where sensitivity to transverse compressional stress is an important design consideration.

IN MANY important applications, magnetic materials in the form of thin laminations are subjected to a compressional stress. Particularly important examples of this type of application are seen in the clamping of magnetic laminations for electric motors, transformers, and synchro components. In each of these examples, the direction of the compressional stress is perpendicular to the direction of the magnetic field and perpendicular to the plane of the laminations; hence, this particular case warrants special consideration.

The effect of transverse compressional stress on ten different specimens of magnetic materials is described. The ten specimens tested were hydrogen-annealed samples of *AEM 4750* (a nickel-iron alloy), 12 Alfenol, and 16 Alfenol (aluminum-iron alloys), 3.5 and 6.4-per-cent silicon-iron, 81 and 90-per-cent nickel-iron, and air-annealed samples of *AEM 4750*, 12 Alfenol, and 16 Alfenol. None of these materials was grain oriented. The specimens tested were laminated toroids with thin paper insulation between the laminations. The toroids measured $1^5/_8$-inch inside diameter and 2.0-inch outside diameter; the lamination and insulating paper thicknesses measured 0.015 and 0.001 inch respectively.

The effect of stress on magnetic properties when the magnetic field is in the same direction as the applied stress has been described by Bozorth[1] and others. For this case it has been found that the sign of the magnetostriction determines whether permeability increases or decreases with a change in stress. When a compressional stress is applied in the same direction as the magnetic field, the permeability will increase with increasing pressure for a material having negative magnetostriction, and the permeability will decrease if the material has positive magnetostriction.

Somewhat different results were observed when the compressional stress was applied perpendicular to the magnetic field. Materials having both negative and positive magnetostriction were tested, and both these classes exhibited a decrease in permeability with increasing pressure. The degree of sensitivity to this transverse compressional stress was dependent on the magnitude of the magnetostriction. It then would be expected that materials having zero magnetostriction should be completely insensitive to pressure changes. Two materials having zero magnetostriction were tested and, except at fields below 0.7 oersted, these materials exhibited essentially no sensitivity to transverse compressional stress. Therefore, the theory that the sensitivity to transverse compressional stress is dependent upon the magnitude of the magnetostriction appears to be substantiated by experiment.

Experimental Procedure

The compressional stress was applied by placing the magnetic laminations in a special fixture, as shown in Fig. 1. By the use of this device, a compressional stress of varying magnitude was exerted on the sample without interfering with the electric windings which are necessary for the determination of magnetic properties.

The device for applying the compressional force was a lever and scale system, as shown in Fig. 2. With this system it was possible to maintain constant pressure on the sample while it was being tested, and it was also possible to increase the compressional stress in increments of 100 psi without relieving the stress while changing from one pressure to another.

Two types of tests were made, and for each test the magnetic properties of the material were measured at compressional stresses of 0, 100, 200, 300, 400, and 500 psi, and the magnetic properties were also measured when the stress was removed. The first of these tests was the standard d-c fluxmeter measurement of maximum permeability, remanence, coercive force, and near saturation flux density, as measured at a field of 30 oersteds.

The second test was made with a-c fields at frequencies of 60 and 400 cps. The purpose of this test was to determine the effect of transverse compressional stress on the a-c magnetization curve and dynamic hysteresis loop. Since the procedure for these a-c measurements is not well known, it will be described briefly here.

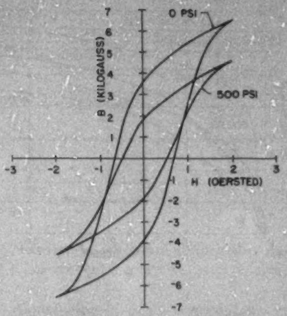

Fig. 5. Dynamic hysteresis loops at a frequency of 60 cps for hydrogen-annealed 90-per-cent nickel-iron at transverse compressional stresses of 0 and 500 psi

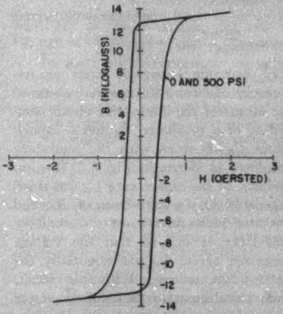

Fig. 6. Dynamic hysteresis loops at a frequency of 60 cps for hydrogen-annealed 6.4-per-cent silicon-iron at transverse compressional stresses of 0 and 500 psi

The circuit for the a-c tests is shown in Fig. 3. The magnetizing field was measured by reading the voltage developed across the metering resistance R_H in the primary circuit. Since the circuit used approximates a voltage source, the current wave is far from being sinusoidal in shape. However, the maximum value of primary current, and therefore H_m, can be determined precisely by means of a peak-reading voltmeter. In terms of the readings of a peak-to-peak voltmeter, H_m is given by

$$H_m = \frac{0.2\pi N_1 V_{p\text{-}p}}{LR_H} \text{ oersted} \qquad (1)$$

where

N_1 = number of primary turns
$V_{p\text{-}p}$ = voltage reading of a peak-to-peak voltmeter
L = mean length of the toroid, centimeters

For toroids of a given mean length L, it is possible and convenient to choose N_1 and R_H so that the peak-to-peak voltmeter reads H_m directly in oersteds.

The value of B_m can be calculated from the voltage reading across the secondary turns N_2 if a rectified average-reading voltmeter is used.[2] This will be true even though (as is actually the case) the flux wave is not sinusoidal in shape. It can be shown that the maximum a-c flux density will be given by

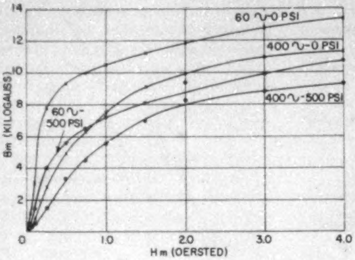

Fig. 7 (left). A-c magnetization curves for hydrogen - annealed AEM 4750

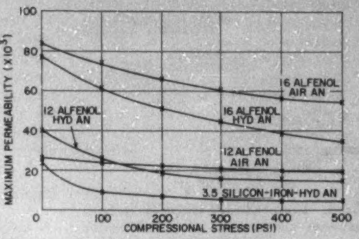

Fig. 9 (right). Maximum permeability (direct current) as a function of transverse compressional stress

$$B_m=\frac{V_{2rms}\times10^8}{\pi\sqrt{2}N_2Af}\text{ gausses}\qquad(2)$$

where

V_{2rms} = voltage as measured by a rectified average-reading voltmeter calibrated in rms voltage of a sine wave

N_2 = secondary turns

A = cross-sectional area of the toroid, square centimeters

f = frequency, cps

The dynamic hysteresis loops at frequencies of 60 and 400 cps were observed by means of the integrating circuit consisting of a resistance R_B and a capacitance C_B in series with the secondary winding, as shown in Fig. 3. The impedance of the capacitance C_B was small compared to the impedance of R_B, and the total series impedance of C_B and R_B was large enough so that the voltage measured across N_2 was essentially the open-circuit voltage. With this circuit, the vertical input on the oscilloscope was proportional to the flux density; and by connecting the horizontal input of the oscilloscope across the metering resistor R_H, the horizontal input was proportional to the magnetic field intensity. Since the values of H_m and B_m were calculated from the voltmeter readings, the vertical and horizontal scales of the oscilloscope were calibrated in terms of kilogausses and oersteds. A calibrated dynamic hysteresis loop was then drawn by photographing the hysteresis loop and using an opaque projector to transfer the photograph onto a sheet of graph paper.

Discussion of Results

Because of limited space, it is not practical to give here all the experimental curves of the various d-c and a-c tests. However, an attempt is made to illustrate with sufficient data the characteristic changes in magnetic properties as a function of transverse compressional stress.

The effect of transverse compressional stress on the a-c properties of a few of the materials tested is shown in Figs. 4 through 8 inclusive. Fig. 4 shows the 400-cps hysteresis loop for the positive magnetostriction material 16 Alfenol at compressional stresses of 0 and 500 psi. The effect of the compressional stress was to cause the dynamic hysteresis loop to become less rectangular. This effect was typical for all the materials tested which had nonzero magnetostriction. Fig. 5 shows the 60-cps hysteresis loop for the negative magnetostriction material of 90-per-cent nickel-iron. When a compressional stress is applied to a material having negative magnetostriction in the same direction as the magnetic field, the exact reverse effect from that shown in Fig. 5 is observed, i.e., the hysteresis loop becomes more rectangular with increasing compressional stress.[3] Fig. 6 shows the 60-cps hysteresis loop for the zero magnetostriction material of 6.4-per-cent silicon-iron. This material showed no measurable change in the size or shape of its dynamic hysteresis loop at values of H_m above 0.7 oersted. The air-annealed samples of 12 Alfenol, 16 Alfenol, and *AEM 4750* showed a smaller change in their a-c hysteresis loops than did the hydrogen-annealed samples of the same material. Since air-annealing in general decreases the magnetostriction, it appears from these a-c data that changes in the magnetic properties caused by transverse compressional stress are dependent on the magnitude and independent of the sign of the magnetostriction.

From Figs. 4 and 5 it appears that the a-c coercive force decreased at a higher value of compressional stress in contradiction to the results of the d-c measurements. This was caused by a lower value of B_m at the compressional stress of 500 psi rather than by a true decrease in coercive force. The accurate comparison of coercive force at different values of compressional stress can be made only when the values of B_m are near saturation and this was not practical to obtain in the a-c tests.

Figs. 7 and 8 show the a-c magnetization curves for hydrogen-annealed *AEM 4750* and 6.4-per-cent silicon-iron. The curve for *AEM 4750* is typical for all

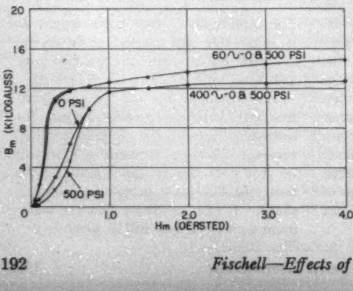

Fig. 8 (left). A-c magnetization curves for hydrogen - annealed 6.4-per-cent silicon-iron

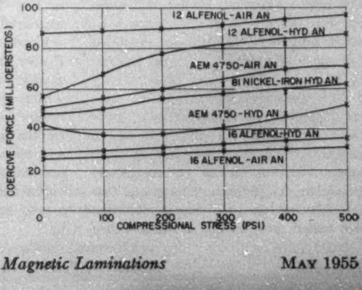

Fig. 10 (right). Coercive force (direct current) as a function of transverse compressional stress

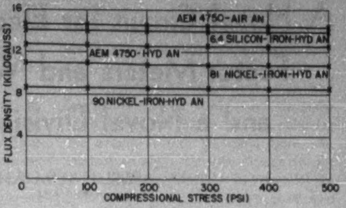

Fig. 12 (right). Flux density at a field strength of 30 oersteds as a function of transverse compressional stress

the materials tested which had nonzero magnetostriction. These curves show that at frequencies of 60 and 400 cps the effect of transverse compressional stress was to decrease the magnetization. Fig. 8, for the zero magnetostriction material 6.4-per-cent silicon-iron shows that, at fields above 0.7 oersted, a change in compressional stress from 0 to 500 psi produced no measurable change in the magnetization curve. A behavior very close to this was observed for the zero magnetostriction material 81-per-cent nickel-iron. Since the magnitude of the magnetostrictive strain varies with field intensity, it is possible that some of the variation in the magnetization curves of 6.4-per-cent silicon-iron and 81-per-cent nickel-iron at fields below 0.7 oersted is caused by the material acquiring some magnetostriction properties at these low field intensities.

The variation of d-c magnetic properties with transverse compressional stress for several of the materials tested is shown in Figs. 9 through 12 inclusive. These figures show that, under the action of an increasing transverse compressional stress, the maximum permeability decreased, the coercive force increased, the remanence decreased, and the near saturation flux density, measured at a field of 30 oersteds, remained virtually unchanged. In the measurements of coercive force and remanence, a maximum field strength of 30 oersteds was used.

Since maximum permeability and coercive force occur at very low field intensities for 6.4-per-cent silicon-iron and 81-per-cent nickel-iron, the changes in these d-c magnetic properties with compressional stress is in line with the changes observed in the a-c properties of these materials at low magnetic field intensities. With the exception of *AEM 4750*, the air-annealed samples showed a smaller percentage change in d-c magnetic properties than did the hydrogen-annealed samples of the same material. The negative magnetostriction material 90-per-cent nickel-iron changed in d-c magnetic properties in the same direction as did the material which had positive magnetostriction. The results of the various a-c and d-c tests are summarized in Table I.

After the stress was removed, the magnetic properties of most of the materials tested returned within a few per cent to their original values. A notable exception was in the measurement of maximum permeability and coercive force for 81 and 90-per-cent nickel-iron. After the stress was removed, the maximum permeability of the 81-per-cent nickel-iron showed a decrease of 9.7 per cent and the coercive force increased 6.5 per cent; the 90 per cent nickel-iron showed a 35-per-cent decrease in maximum permeability and a 23-per-cent increase in coercive force.

Table I. Percentage Change in Magnetic Properties Resulting from an Increase in Transverse Compressional Stress from 0 to 500 Psi

			Percentage Change from 0 to 500 Psi					
Material	Anneal	Magnetostriction Constant	B_m (60 Cycles)	B_m (400 Cycles)	B_m (d-c)	Maximum Permeability	Remanence	Coercive Force
12-Alfenol	hydrogen	+	38.3	35.2	6.42	64.2	28.1	48.4
12-Alfenol	air	+	21.0	20.3	5.28	27.1	18.5	10.0
16-Alfenol	hydrogen	+	18.4	17.8	5.13	58.6	30.9	27.1
16-Alfenol	air	+	7.42	7.20	1.46	34.9	14.0	26.7

AEM-4,750	air	+	24.1	17.6	2.87	67.0	49.7	41.5
3.5-per-cent silicon-iron	hydrogen	+	40.4	20.8	0.27	81.9	75.4	31.2
6.4-per-cent silicon-iron	hydrogen	0	0	0	0.86	9.25	2.48	12.5
81-per-cent nickel-iron	hydrogen	0	1.04	1.54	2.73	51.4	24.9	29.4
90-per-cent nickel-iron	hydrogen	−	25.7	16.6	3.00	50.8	65.0	4.88

Conclusion

Several conclusions can be drawn regarding the sensitivity of magnetic materials to a transverse compressional stress.

1. Variations in magnetic properties are dependent on the magnitude and not on the sign of the magnetostriction constant.
2. For materials having nonzero magnetostriction, under the action of an increasing transverse compressional stress, the maximum permeability decreased, the coercive force increased, the remanence decreased, the flux density near saturation remained virtually unchanged, and, for a constant value of H_m, the maximum a-c flux density decreased.
3. The magnetic characteristics of materials having zero magnetostriction remain virtually unaltered by transverse compressional stress except at very low fields.

The results of this paper can be applied in choosing a magnetic material for a particular application where sensitivity to transverse compressional stress is an important design consideration. In the manufacture of precision components using magnetic laminations, differences in clamping pressures may cause variations in magnetic properties if the material used has a high sensitivity to transverse compressional stress. Variations in magnetic properties from one set of laminations to another can be minimized by using stress-insensitive magnetic materials. The high values of maximum permeability and saturation flux density of 6.4-per-cent silicon-iron make it a particularly interesting magnetic material where stress insensitivity is desired.

A Novel Circuit for Electronic Power-Factor Meters and Wattmeters, and a Novel Division Device

M. ABDEL-HALIM AHMED
MEMBER AIEE

Synopsis: Three novel electronic measuring instruments are presented, which may be used to measure power, power factor (pf), voltage, current, or impedance. They use two tubes, operated as cathode followers, in a push-pull fashion, so that the inherent property of a wide-range linear characteristic is employed to advantage. The new principle underlying the operation of the tubes involves the commutation of their currents in alternate half-cycles by means of a square-wave generator. The resulting average plate current is a direct measure of the product $I \cos \varphi$. A rectifier gives a direct current proportional to the alternating voltage, and an electrodynamic instrument multiplies the two direct currents, thus giving a direct reading of the power. For the direct reading of pf, two direct currents are obtained, one being proportional to the product $V \cos \varphi$ and the other proportional to V. Their quotient is a direct measure of $\cos \varphi$. The division is effected by means of a twin logarithmic d-c instrument having a movable scale. The instruments are characterized by their simplicity, reliability, high accuracy, and stability. They have exceptionally good features and predictable performance over a frequency range extending from the lowest power frequencies to a predicted value of about 30 megacycles (mc) when using high-frequency tubes; the main limiting factor being the stray capacities across the output of the square-wave generator. There are, however, some other factors which tend to lower this operating limit, and 10 mc is considered a reasonable higher limit.

THE DIRECT measurement of power at power frequencies and the lower audio frequencies is most conveniently carried out by using an electrodynamic instrument. Alternatively, a double-magnet induction instrument may be used at power frequencies. For the measurement of small amounts of power, or for audio- and high-frequency work, these instruments are not suitable, owing to their well-known inherent drawbacks. For such cases, many indirect methods have been devised, but even then, the pf of the circuit has to be already known.

Many investigators have suggested different instruments which they have claimed to be suitable for the direct measurement of power at high frequencies. A number of the early attempts involve the use of two similar square-law elements, which may be thermal (hot-wire or thermocouple elements) or electronic tubes working in the square-law range of their characteristics.[1–4] In a later attempt[5] the tubes were operated in their logarithmic range. All these devices have the following disadvantages: the two nonlinear elements have to be exactly matched, which is difficult to perform; replacement of the elements will affect the calibration; and the circuits require frequent adjustment. As regards the electronic tubes, even when matched, the desired relation of their characteristics holds only over a limited range. Voltage dividers will thus be unavoidable, and these cause undue insertion loss in the circuit, and trouble at high frequencies. Moreover, the dissipation loss of the current circuit has to be high if any reasonable accuracy is to be expected, especially with the thermal devices. Supply voltage variations, besides causing calibration errors, require frequent adjustment of the zero setting. For all the square-law devices, the insertion unit is of T- or π-configuration, with which it is difficult to provide a satisfactory ground system.

Among others, there are the following three distinct classes of device:

1. *Devices using electrostatic methods.* These are not handy and are too delicate. Difficulty is encountered in their adjustment and setting, and they require high voltages for their operation.

2. *Devices using oscillographs.* These either measure instantaneous values of power or give an indirect measure of the average value through tedious and inaccurate operations. They also suffer from lack of sensitivity.

3. *Devices using multielectrode tubes.*[6–8] The tubes are arranged to operate on the linear parts of their various grid characteristics, which are too small to avoid rectification, and the instruments were found to give readings with current or voltage alone, even with push-pull operation. Discrepancies in the characteristics of individual tubes of a given type are serious, and the choice of matched tubes is too difficult. Frequent check calibration and zero-setting adjustment are necessary. The use of a voltage divider, with its inherent disadvantages, is unavoidable.

To this class a new instrument having improved features has been recently added.[9] The tubes operate in the exponential range of their characteristics. However, this device still suffers from the disadvantages of a limited operating range for the control grid voltage, and from the fact that it cannot be used for circuits having voltages below 20 volts (transformers can be used at low frequencies since the input is of high impedance, but this is not a possible solution at the higher frequencies). The requirement of recalibration when replacing tubes, the necessity of stabilized-supply or battery operation, and the unavoidable rectification errors (though claimed to be small) resulting from the discrepancy of the parameters of the tubes themselves from the requisite values under this mode of operation, are all inherent disadvantages.

There is no known method for the direct measurement of the power factor, $\cos \varphi$, at frequencies above power frequencies. However, the phase displacement φ may be measured by the commonly used phase detectors, in which two constant-amplitude square-wave signals are applied to two elements of a tube. The output produced is a function of the phase difference between the square-wave signals. If the instrument is to be calibrated to read pf the scale would be crowded in its lower part. Besides, this type of instrument is essentially complicated.

The instruments described in this paper use two tubes operating in push-pull and working mainly on the linear parts of their characteristics, which usually cover a wide range. This range can be extended and made as linear as desired by suitable adjustments of the external circuit, thus rectification errors are almost eliminated and voltage dividers are dispensed with. Critical adjustment of the circuit elements is not a necessity in this mode of operation. Negative current feedback is used with advantage, which results in extended linear range, increased stability, less trouble with tube replacements, and insensitivity of calibration and zero setting to supply voltage variations.

The instruments are characterized by their simplicity in theory, circuit design, operation, and adjustment. Almost any tube type can be used, and the performance can be readily predicted from knowledge of the normal tube parameters and circuit elements. A unique main feature lies in the fact that individual d-c components which are proportional to the individual a-c compo-

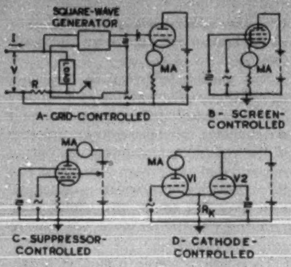

Fig. 1. Principle of the I cos φ meter

nents are available in the circuit, so that direct readings of voltage, current, pf, and power can be readily obtained with the same instrument with complete reliability and stability. Furthermore, the instruments are suitable for measurements at very low pf. They will therefore be found useful in measuring impedance/frequency and pf/frequency characteristics of a network or apparatus under actual operating conditions.

Among the good features of the instruments are the uniform scale of the indicating instrument, the low insertion loss of the series resistor in the current circuit, the high accuracy, and the simplicity of adapting the instrument for multirange use.

For unavoidable reasons relating to the lack of certain equipment, stress was given to obtaining the maximum possible output power from the tubes, which forced the use of normal receiving tubes. However, with the use of high-frequency tubes, it is shown that a frequency range comparable with any other type of instrument can be covered. Predicted higher limits of about 30 mc at unity pf and 3.5 mc at zero pf were obtained. Nevertheless, factors not considered are expected to cause trouble at the higher frequencies, especially with the square-wave generator, and 10 mc is considered a reasonable higher limit. The errors resulting from other possible sources are discussed and found remarkably small.

Three types of the instruments have been developed: the grid-controlled type; the suppressor-controlled type; and the cathode-controlled type.

General Outline

The main idea of these commutating type of instruments lies in using an electronic tube having a fairly linear transfer characteristic of control-grid voltage versus plate current, which is readily obtained through the use of negative current feedback. Then a signal is applied to the control grid, and the tube current is commutated only during a proper interval of its cycle. The commutation period is controlled by applying a square-wave signal having the same frequency as the control-grid signal, and of sufficient amplitude, to one of the tube grids, thus allowing the plate current to flow during only one half of the square-wave cycle. The average value of the plate current follows, linearly, the signal amplitude and the cosine of the phase angle between the signal and the square wave. The square-wave voltage is obtained from a square-wave generator designed so that its output is of the same frequency as, and in phase with, the voltage applied to its input.

Fig. 1(A) shows the circuit arrangement for the measurement of pf, using a triode. The voltage V across the load is applied to the input of the square-wave generator, the square-wave output of which is applied to the control grid of the tube. The voltage drop IR across a small resistance R in which the load current passes, is applied to the control grid of the tube, superposed on the square wave. The change in the average value of the output current will be proportional to $I \cos \varphi$, φ being the phase angle between V and I. If I is known or measured (which can be done by the same instrument), or if the voltage IR is adjusted to a predetermined value, of if a suitable dividing circuit is added to give the quotient of the two quantities $I \cos \varphi$ and I, the device will give a direct reading of $\cos \varphi$.

It is obvious that if the input to the square-wave generator were derived from the load current circuit, $\cos \varphi$ would be unity, and the device an ammeter with a linear scale. In the same manner, if the signal applied to the grid of the tube were derived from the voltage circuit, the device would be a voltmeter with a linear scale.

Now, for the measurement of power, the product $I \cos \varphi$ has already been obtained in the form of a direct current, and it now remains to obtain a direct current proportional to V through the use of a conventional rectifying circuit. The two direct currents are multiplied most easily by the use of an ordinary electrodynamic instrument, and the device is then a direct-reading wattmeter with a linear scale.

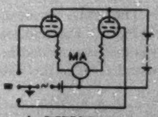
That it is not possible to connect the tube d-c supply voltage to ground is the main inconvenience noticed in the grid-controlled circuit. However, in many instances this is not a serious defect, especially if it is noted that this voltage is raised above ground by only a fraction of a volt, the usual value of the voltage drop IR.

In some circuit arrangements, especially in high-frequency work, and in order to provide a suitable grounding point for the circuit, it may be found more convenient to apply the two signals to different grids of the tube. In Fig. 1(B) the square-wave signal is applied to the screen grid of a pentode whose suppressor grid is internally connected to the cathode. With this procedure, severe requirements are imposed on the square-wave generator, which must provide a positive wave of large magnitude and be capable of supplying the screen-grid current of the tube; moreover, if a push-pull arrangement is used, both sides of its output should give exactly equal amplitudes of the square wave.

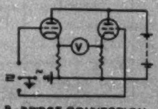
In Fig. 1(C) the square wave is applied to the suppressor grid of a pentode. It requires a square-wave generator giving a negative signal, and thus precludes all these difficulties.

In Fig. 1(D) two tubes are used having a common cathode resistor, which may be triodes or multigrid tubes. Each signal is applied to the control grid of one tube. When $V2$ is conducting, the voltage drop across the common cathode resistor R_K will cause $V1$ to be biased beyond cut-off; when $V2$ is cut-off, $V1$ will be conducting. This circuit has the advantage that it requires a square wave of small amplitude, and will consequently be suitable for use at much higher frequencies.

All circuit arrangements are well adapted for use in a push-pull fashion. This is shown in Fig. 2 for the grid-controlled type. A differential-wound d-c indicating instrument can be used as in Fig. 2(A), or a normal instrument may be used as in Fig. 2(B). It is obvious that in the differential connection the instrument should have a low impedance to the al-



A- DIFFERENTIAL CONNECTION



B- BRIDGE CONNECTION

Fig. 2. Principle of the push-pull I cos φ meter

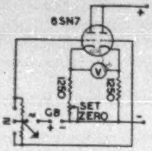


Fig. 3. The grid-controlled I cos φ meter

ternating current. Its coils may be conveniently shunted with capacitors, provided their d-c resistances are relatively low. For the bridge connection, the circuit between the two cathodes should offer high impedance to both alternating and direct currents. When the resistance of the instrument is low, an external resistance may be added in series with it, and the coil may also be shunted with a capacitor.

The use of a push-pull circuit has the merits of obviating the necessity of compensating the zero-signal tube current, reducing zero-setting variations with supply voltage variations, reducing the errors resulting from any possible nonlinearity in the tube characteristics and, finally, increasing the sensitivity of the instrument, thus reducing the insertion loss of the series resistance in the load current circuit.

The merits of the cathode-follower circuit are well known. Its main advantages relating to the present type of work lie in providing a wide-range linear-transfer characteristic, whose slope depends mainly on the value of the cathode resistor and is almost independent of the tube parameters, reducing tube current variations with supply voltage variations. Therefore no readjustment or recalibration is necessary when replacing tubes, no readjustment of zero setting is necessary during operation, and the stability of the readings is highly increased.

Grid-Controlled Commutating PF Meter

CIRCUIT

The actual circuit of this type is shown in Fig. 3. For zero setting, a variable resistance is provided in one of the cathode circuits. The d-c characteristic for one triode section is shown in Fig. 4. It has a linear range beginning from −4 volts upward. The upper limit of the useful working range is about +20 volts, at which point the grid-cathode potential is zero. The operating point is chosen at about the middle of the useful working range, hence a positive bias (i.e., connected with its positive side toward the grid of the tube) of about 8 volts is required. An a-c signal up to a 12-volt peak (8.5 volts rms) can be applied to the control grid.

The push-pull square-wave generator has to carry the grid potential in the negative direction so that the tube is cut off with the maximum value of the a-c signal, and thus the square-wave generator will give, from each side of its output, zero potential during 1/2 cycle and a negative potential of more than 32 volts during the other 1/2 cycle. It is not essential that both sides should give equal negative voltages.

SQUARE-WAVE GENERATOR

The circuit of the square-wave generator, which is simple and direct, is shown in Fig. 5. Clipping is done by the double-diode clipper tubes as well as by the amplifier stages. The amplifier stages work with almost zero grid bias at no signal, and when the signal is applied, they are automatically biased to about the peak value of the signal through grid-leak rectification action. The negative peak value of the signal is sufficient to bring the amplifier tube to cutoff. By this means, the amplifier stages help also in clipping off the higher portions of the signal, in which the effect of stray capacities appears most, leaving the signal with steep sides. Thus by these successive clipping operations, the effects of stray capacities can be neglected in all the stages prior to the grids of the output tubes. Effects of stray capacities in the output circuit, however, will remain as the main limiting factor of the frequency range in which the square-wave generator may be used, since no clipping stage follows.

That the signal applied to the grid of a tube must be more than sufficient to bring it to cutoff is most important in the output stage, since it is extremely necessary for the satisfactory operation of the pf meter that both tubes will begin from the same predetermined working point, and thus the square-wave generator has to give a signal which falls down to exactly zero.

It is possible to extend the frequency range through the addition of a clipping stage, the use of high-frequency tubes for the pf meter, minimizing stray capacities of the connections, reducing the output resistance of the square-wave generator through the use of high plate voltages and more powerful tubes, and adding compensating inductances in the square-wave generator circuit.

There are, however, a number of factors which cause trouble at high frequencies in the square-wave generator, and therefore tend to lower its useful upper frequency limit further than would be predicted by consideration of the effect of stray capacities across the output circuit alone. Such factors are, for example, the inductance in tube element leads, the cathode-to-ground capacitance, balance on clipping diodes, and phase shift in clipping stages. Balance on the clipping diodes is, however, not an essential requirement, since it is not necessary that the push-pull output be of the same magnitude on both sides, as long as the magnitudes are enough to bring the commutating tubes to cutoff with the maximum value of applied a-c signal voltage.

Trouble from phase shift in the various stages of the square-wave generator can be eliminated by adding at its input a compensating simple resistance-capacitance phase-shifting circuit. Before measurements at high frequencies are started, the instrument is switched so as to read either *V* or *I*, and the compensating circuit is adjusted for maximum reading on the indicating instrument.

The square-wave generator is suitable for use with input voltages covering a very wide range, from a fraction of a volt to several hundred volts, and can therefore be connected directly to the load voltage circuit without the necessity of using a voltage divider. The input circuit has a high impedance which causes no appreciable insertion loss. However, if a much higher input impedance is desired, or if it is required to work with very small input voltages, a single-tube conventional amplifier stage can be added at the input. This may use a cathode-follower circuit if the input voltage is not too low.

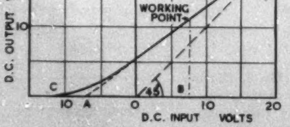

Fig. 4 (left). Static characteristic for one triode section of Fig. 3

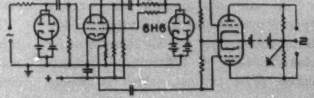
Fig. 5 (right). Square-wave generator for use with the grid-controlled I cos φ meter



The square-wave generator must give equal intervals of its two output waves. This can be easily checked by applying the square-wave voltages alone to the pf meter, which should then show no indication. Errors in timing may be caused by harmonics existing in the input voltage when these harmonics are not in phase or in antiphase with the fundamental. These errors increase with the harmonic per cent (%) and the phase difference between the harmonic and the fundamental, and decrease for harmonics of higher order.

To have an idea of the error in timing produced by harmonics that occur in practical cases, consider, for example, the case of a class-*C* amplifier driven from a sinusoidal source and the output is a tuned load. This circuit operates with almost unity pf. It can be shown that the ratio of the tuned load impedance Z_h at the frequency of the *n*th harmonic, to its impedance Z_f at the fundamental frequency, is given by

$$\frac{Z_h}{Z_f}=\frac{1}{1+jQ\dfrac{n^2-1}{n}}$$

where Q represents the Q-factor of the tuned load. With a pessimistic low value of Q, say 20, the foregoing ratio would amount to 3.33% for the second harmonic, 1.87% for the third, and so on, while the phase angle is almost 90 degrees. With a current flow of 100 degrees in the class-*C* amplifier and three-halves law, the current flowing in the tuned load will have 83.5% second harmonic and 57% third harmonic. Therefore the voltage developed across the tuned load will have harmonics of the order of 2.78% and 1.065% respectively. These will produce an error in timing of about 1.6 degrees and 0.6 degree respectively.

It should still be pointed out that a timing error or a phase shift which arises from an even-order harmonic can always be totally eliminated by applying a small adjustable direct voltage at the input of the square-wave generator, superposed on the alternating voltage.

OPERATION OF PF METER

Ideal Operation

In this case it is assumed that the two tubes have identical and exactly linear transfer characteristics down to the cutoff point. The magnitudes of the applied signals are such that in the half-cycle when the square-wave voltage is zero, the a-c signal will drive the grid of the tube neither more positive than the cathode nor more negative than the cutoff point; and in the other half-cycle, when the square-wave voltage is negative, the a-c signal will not drive the grid more positive than the cutoff point.

Let S denote the slope of the transfer characteristic of either tube which can be as

$$\frac{\mu}{\mu+1}\,\frac{1}{R_k+\dfrac{\rho+R_a}{\mu+1}}$$

where

μ = amplification factor
ρ = plate internal impedance
R_a = plate load impedance
I_0 = steady no-signal plate current of either tube
T = time period of 1 cycle $=1/f=2\pi/\omega$, f being the frequency
$F\sin(\omega t-\varphi)$ = a-c signal applied to the grid, φ being the phase angle between this signal and the square-wave signal
I_1 and I_2 = average currents of the two tubes when the signals are applied

then

$$I_1=\frac{1}{T}\int_0^{T/2}[I_0+SF\sin(\omega t-\varphi)]dt$$
$$=\frac{I_0}{2}+\frac{S}{\pi}F\cos\varphi$$

$$I_2=\frac{1}{T}\int_{T/2}^{T}[I_0+SF\sin(\omega t-\varphi)]dt$$
$$=\frac{I_0}{2}-\frac{S}{\pi}F\cos\varphi$$

and the average current difference is given by

$$I=I_1-I_2=(2S/\pi)F\cos\varphi \qquad (1)$$

which is proportional to the product of the magnitude of the applied a-c signal and the pf.

Effect of Different Transfer Characteristic Slopes

In a cathode-follower circuit, the tube current is almost independent of the tube parameters, and the slope of the transfer characteristic S is mainly defined by the value of R_k. However, if for any reason the two tubes give different transfer characteristic slopes, say S_1 and S_2, the reading of the indicating instrument will be

$$I=\frac{S_1+S_2}{\pi}F\cos\varphi \qquad (2)$$

i.e., the average value $(S_1+S_2)/2$ is to be considered instead of S, and the reading is still proportional to the product of the magnitude of the a-c signal and the pf.

Effect of Error in Square-Wave Timing

It has been stated that the square-wave generator can, in most cases, be adjusted to give exact timing. However, it is interesting to show that even without such an adjustment, the error produced in the pf meter indication is very small.

If T_1 and T_2 are the time intervals of the square wave, so that $T_1+T_2=T$, and writing $\omega T_1=\pi+\delta$, $\omega T_2=\pi-\delta$, or $\omega(T_1-T_2)=2\delta$, then, when the square-wave signal only is applied, the indicating instrument reads $I_0(T_1-T_2)/T=I_0(\delta/\pi)$.

When the signal $F\sin(\omega t-\varphi)$ is applied

$$I=\frac{1}{T}\int_0^{T_1}[I_0+SF\sin(\omega t-\varphi)]dt-$$
$$\frac{1}{T}\int_{T_1}^{T}[I_0+SF\sin(\omega t-\varphi)]dt$$
$$=I_0\frac{\delta}{\pi}+\frac{S}{\pi}F[\cos\varphi-\cos(\omega T_1-\varphi)]$$

and the change in the reading is then given by

$$\frac{S}{\pi}F[\cos\varphi-\cos(\omega T_1-\varphi)]$$
$$=\frac{S}{\pi}F[\cos\varphi+\cos(\varphi-\delta)] \qquad (3)$$

Compare this with equation 1, and the error in the reading will be

$$\frac{S}{\pi}F[\cos\varphi-\cos(\varphi-\delta)]$$

and the relative error is

$$\frac{\cos\varphi-\cos(\varphi-\delta)}{2\cos\varphi}=\frac{1}{2}\tan\varphi\sin\delta-\sin^2\frac{\delta}{2}$$

and, since δ is always very small

$$\text{relative error}\cong\frac{\delta}{2}\tan\varphi-\frac{1}{4}\delta^2$$

This error would naturally be infinite at zero pf, since the true reading should have been zero. However, this is no indication of the error, and the error in indicating instruments is usually, and preferably, judged by referring to the maximum instrument reading, $(2S/\pi)\,F_{\max}$; hence

full-scale relative error

$$=\frac{F}{F_{\max}}\,\frac{\cos\varphi-\cos(\varphi-\delta)}{2}$$

and for the extreme condition when $F=F_{\max}$ (=12 volts)

full-scale relative error

$$=\frac{1}{2}[\cos\varphi-\cos(\varphi-\delta)]$$
$$=\sin\frac{\delta}{2}\sin\left(\varphi-\frac{\delta}{2}\right)\cong\frac{\delta}{2}\sin\left(\varphi-\frac{\delta}{2}\right)$$

For the previously estimated value of $\delta=1.6$ degrees, this error amounts to 0.02% at unity pf and 1.38% at zero pf.

Further, consider a much exaggerated value of 10% third harmonic, the timing error in this case is 5.5 degrees, which, in the extreme case when $F=F_{\max}=12$ volts,

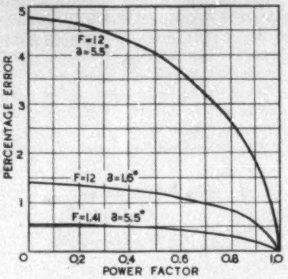


Fig. 6. Full-scale relative error attributable to imperfect square-wave timing

produces a relative error of only 0.23% at unity pf and 4.8% at zero pf. Yet, for a small insertion loss of the current element in the load circuit, the a-c signal should never exceed 1 volt rms, i.e., $F=1.41$ volts, and in this case the relative error amounts to 0.027% and 0.565% respectively.

Fig. 6 shows this error for different pf in the three cases considered in the foregoing, from which it is concluded that this error, if it exists, is always small or negligible.

Effect of Nonlinearity in Transfer Characteristics

Consider first that the nonlinearity occurs all over the working range of the characteristic, then this latter can be expressed in the form

$$i=I_0+Sv+Pv^2$$

This expression assumes symmetrical deviations from a straight-line relation, since it neglects the cubed-voltage term and terms of higher order. This assumption is justified mainly owing to the large amount of negative feedback present, and also owing to the relatively low value of a-c signal voltage that would be allowed compared to the linear part of the characteristic (Fig. 4). It is well known that negative feedback considerably reduces the nonlinear terms of the characteristic, even when large excursions on the characteristic are considered, and that the amount of reduction increases rapidly with the order of the nonlinear term.

When an a-c signal of the form $v=F\sin(\omega t-\varphi)$ is applied, then

$$I_1=\frac{1}{T}\int_0^{T/2}[I_0+SF\sin(\omega t-\varphi)+PF^2\sin^2(\omega t-\varphi)]dt$$

$$=\frac{I_0}{2}+\frac{S}{\pi}F\cos\varphi+\frac{PF^2}{4}+\frac{PF^2}{4\pi}\sin 2\varphi$$

$$I_2=\frac{1}{T}\int_{T/2}^{T}[I_0+SF\sin(\omega t-\varphi)+PF^2\sin^2(\omega t-\varphi)]dt$$

$$=\frac{I_0}{2}-\frac{S}{\pi}F\cos\varphi+\frac{PF^2}{4}+\frac{PF^2}{4\pi}\sin 2\varphi$$

and the instrument reading will be

$$I=\frac{2S}{\pi}F\cos\varphi \tag{4}$$

This is the same as equation 1, and thus no error is produced, a result to be expected from the push-pull operation of the circuit.

It is more common for the transfer characteristic to be linear along its upper part, and to show nonlinearity only in the lower part. In an exaggerated case where the nonlinearity is assumed to extend up to the static working point of the characteristic (when this is not the case, a smaller error would be expected), this latter can be divided into two portions, which may be expressed as $i=I_0+Sv$ for positive values of the input voltage v, and $i=I_0+Sv+Pv^2$ for the negative values of v.

Now, for the first tube, which is conducting in the time period 0 to π/ω, the applied voltage is $v=F\sin(\omega t-\varphi)$, which will then be negative in the time period 0 to φ/ω and positive in the time period φ/ω to π/ω. The average current of this tube is thus given by

$$I_1=\frac{1}{T}\int_{\varphi/\omega}^{\pi/\omega}[I_0+SF\sin(\omega t-\varphi)]dt+\frac{1}{T}\int_0^{\varphi/\omega}[I_0+SF\sin(\omega t-\varphi)+PF^2\sin^2(\omega t-\varphi)]dt$$

$$=\frac{I_0}{2}+\frac{S}{\pi}F\cos\varphi+\frac{PF^2}{4\pi}\varphi+\frac{\sin 2\varphi}{2}$$

For the second tube, which is conducting in the period π/ω to $2\pi/\omega$, the voltage $v=F\sin(\omega t-\varphi)$ is positive in the time period π/ω to $(\pi/\omega+\varphi/\omega)$, and negative in the time period $(\pi/\omega+\varphi/\omega)$ to $2\pi/\omega$, hence

$$I_2=\frac{1}{T}\int_{\pi/\omega}^{\frac{\pi}{\omega}+\frac{\varphi}{\omega}}[I_0+SF\sin(\omega t-\varphi)]dt+\frac{1}{T}\int_{\frac{\pi}{\omega}+\frac{\varphi}{\omega}}^{2\pi/\omega}[I_0+SF\sin(\omega t-\varphi)+PF^2\sin^2\omega t-\varphi)]dt$$

$$=\frac{I_0}{2}-\frac{S}{\pi}F\cos\varphi+\frac{PF^2}{4\pi}\left(\pi-\varphi+\frac{\sin 2\varphi}{2}\right)$$

The instrument indication will then be

$$I=\frac{2S}{\pi}F\cos\varphi\left[1+\frac{P}{4S\cos\varphi}F\left(\varphi-\frac{\pi}{2}\right)\right] \tag{5}$$

Hence the relative error resulting from nonlinearity is given by

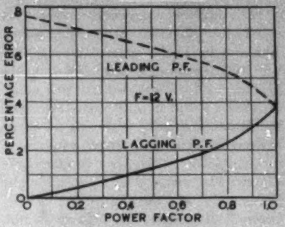

Fig. 7. Full-scale relative error attributable to characteristic nonlinearity

$$\text{relative error}=-\frac{PF}{4S\cos\varphi}\left(\varphi-\frac{\pi}{2}\right)$$

This is seen to be proportional to the amplitude of the applied signal, and is not infinite at zero pf.

The ratio P/S can be shown geometrically to be equal to $\overline{CA}/\overline{CB}^2$ (see Fig. 4), which amounts to 0.008. If an extreme case is considered, when $F=12$ volts, the relative error is shown in Fig. 7 for different power factors. It should be pointed out that although these values are small, they are still too much exaggerated in two ways, the first in considering the nonlinearity to extend up to the steady no-signal working point, and the second in taking $F=12$ volts, while it does not usually exceed a fraction of a volt.

Effect of Harmonics in Load Current Wave Form

Let the a-c signal voltage, in this case, be expressed in the form

$$v=F_1\sin(\omega t-\varphi)+F_n\sin(n\omega t-\varphi_n)$$

where n is the order of the harmonic.

Consider a perfect square wave and a linear characteristic; then

$$I_1=\frac{1}{T}\int_0^{\pi/\omega}[I_0+SF_1\sin(\omega t-\varphi)+SF_n\sin(n\omega t-\varphi_n)]dt$$

$$=\frac{I_0}{2}+\frac{S}{\pi}F_1\cos\varphi \text{ when } n \text{ is even, or}$$

$$\frac{I_0}{2}+\frac{S}{\pi}F_1\cos\varphi+\frac{S}{\pi}\frac{F_n}{n}\cos\varphi_n \quad \text{when } n \text{ is odd}$$

and

$$I_2=\frac{1}{T}\int_{\pi/\omega}^{2\pi/\omega}[I_0+SF_1\sin(\omega t-\varphi)+SF_n\sin(n\omega t-\varphi_n)]dt$$

$$=\frac{I_0}{2}-\frac{S}{\pi}F_1\cos\varphi \text{ when } n \text{ is even, or}$$

$$\frac{I_0}{2}-\frac{S}{\pi}F_1\cos\varphi-\frac{S}{\pi}\frac{F_n}{n}\cos\varphi_n \quad \text{when } n \text{ is odd}$$

and the instrument indication will thus be

$$I=\frac{2S}{\pi}F_1\cos\varphi \text{ when } n \text{ is even, or}$$

$$\frac{2S}{\pi}F_1\cos\varphi+\frac{2S}{\pi}\frac{F_n}{n}\cos\varphi_n \text{ when } n \text{ is odd}$$

It is thus seen that the even harmonics produce no effect whatever. The odd harmonics, however, produce an error whose relative value is given by

$$\frac{F_n}{nF_1}\frac{\cos\varphi_n}{\cos\varphi}$$

For a given value of cos φ, this error is maximum when $\varphi_n=0$, and the full-scale relative error (referred to the maximum instrument reading, i.e., at unity pf) will then be F_n/nF_1. Hence, for an exaggerated value of 10% harmonic content, the maximum error amounts to 3.33% for the third harmonic, 2% for the fifth harmonic, etc.

It is therefore concluded that errors produced by harmonics, whether in the current or voltage wave forms, are either zero or negligible.

Effect of Stray Capacities

The square-wave generator forms that part of the circuit which limits the useful frequency range. The presence of stray capacities across its output represents the main factor limiting the highest operating frequency. The effect of such stray capacities will be predicted in the following. However, other factors not considered, which cause trouble at high frequencies, such as lead and tube inductances, cathode-to-ground capacitances, etc., will tend to reduce the predicted values. Nevertheless, it is believed that by careful circuit design and choice of suitable tubes, the predicted limits can be closely preserved.

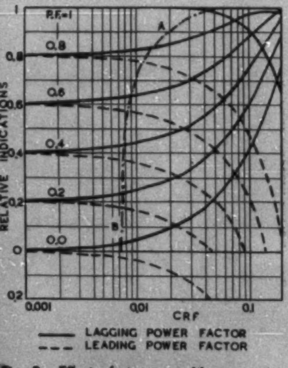

Fig. 8. Effect of stray capacities on meter readings (theoretical)

The presence of a stray capacity C across the output resistance R of the square-wave generator will cause a gradual exponential building up and decay of the voltage, instead of an instantaneous one. With the square-wave voltage applied alone, and with no a-c signal, it can be shown that the average tube currents I_1 and I_2 are given by

$$I_1=I_2=\frac{I_0}{2}\left[1+2CRf\left(\ln\frac{V_c}{E-V_c}-\frac{E}{V_c}\ln\frac{E}{E-V_c}+\frac{E}{V_c}\epsilon^{-\frac{1}{2CRf}}\right)\right]$$

where

f = frequency
V_c = cut-off voltage of the tube
E = amplitude of the square-wave voltage

If, as usual, E is made $2V_c$, then

$$I_1=I_2=\frac{I_0}{2}\left[1+4CRf\left(\epsilon^{-\frac{1}{2CRf}}-0.6931\right)\right]$$

The zero setting is thus not affected by the increase of frequency or stray capacity, but the average current of each tube decreases. It becomes 86% of its value at low frequencies when CRf is increased to 0.05.

When a small a-c signal of the form $F\sin(\omega t-\varphi)$ is applied, the instrument indication can be shown to be

$$I=\frac{S}{\pi}F\left[\cos\left(\varphi-2\pi CRf\ln\frac{E}{E-V_c}\right)+\cos\left(\varphi-2\pi CRf\ln\frac{E}{V_c}\right)\right] \quad (6)$$

and when $E=2V_c$, this becomes

$$I=\frac{2SF}{\pi}\cos(\varphi-4.354CRf) \quad (7)$$

hence

$$\text{relative error}=1-\frac{\cos(\varphi-4.354CRf)}{\cos\varphi}$$

It is seen that the error is independent of the signal amplitude, but depends on the value of the product CRf. Fig. 8 gives the instrument indication at different pf as CRf increases, calculated from equation 7. The curve AB gives the limiting values of CRf if the error is not to exceed 3% of full scale. This gives a value of $CRf=0.0565$ at unity pf and 0.007 at zero pf. With acorn triodes in a cathode-follower circuit, and with proper layout, the value of C can be kept as low as, say, 10 micromicrofarads. Since R is of the order of 1,000 ohms, the instrument is suitable for use at frequencies as high as 5.65 mc at unity pf and 0.7 mc at zero pf. However, equation 6 shows that these values can be increased by increasing E.

Suppressor-Controlled Commutating PF Meter

In the suppressor-controlled commutating pf meter, the square wave is impressed on the suppressor grid of a pentode. When the suppressor grid is driven negative, the anode current falls. The screen-grid current rises, and may attain values in excess of the safe limit. Therefore the developed circuit has in view two purposes: to limit the maximum value of the screen-grid current by lowering the screen potential when the plate current is suppressed, and to make use of the rise of the screen current in increasing the sensitivity. The circuit developed to achieve these two functions is shown in Fig. 9. The screen grid of each tube is cross-connected to the plate of the other tube. Now, when one tube is commutating, the other is suppressed. The plate current of the commutating tube, as well as the relatively high screen current of the suppressed tube, both flowing in the plate-load resistor of the commutating tube, will cause a large voltage drop, so that the voltage at the screen grid of the suppressed tube is largely reduced. The commutating tube, however, has its screen grid connected to the plate of the suppressed tube. Only the relatively small screen current of the commutating tube flows in the plate resistor of the suppressed tube, so that the voltage at the screen grid of the commutating tube is only slightly less than the full d-c supply voltage of the circuit, and thus almost the normal plate current of the commutating tube is obtained. These operations are reversible in each half-cycle of the square wave, so that the suppressed tube will always have a low screen-grid potential and the commutating tube a high screen-grid potential. By making use of the screen-grid currents, an increase of more than 50% in the sensitivity of the instrument has been obtained.

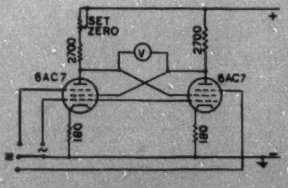

Fig. 9. The suppressor-controlled I cos φ meter

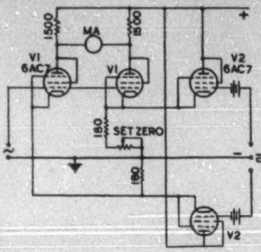

Fig. 10. The cathode-controlled I cos φ meter

The square-wave generator used with this type is essentially the same as that shown in Fig. 5, with minor modifications which mainly imply the addition of a push-pull amplifier stage at the output to cope with the required higher amplitude of the square wave. Mathematical analysis of the circuit is carried out on almost the same lines as for the grid-controlled type, and yields almost similar results.

Cathode-Controlled Commutating PF Meter

The main feature of the cathode-controlled commutating pf meter is that it allows the use of small a-c and square-wave signals, while these are applied to different tube electrodes to allow a suitable grounding point of the system.

Fig. 10 shows the circuit developed for push-pull operation. A common cathode resistor for each pair of tubes *V*1 and *V*2 is used. Tubes *V*2 are biased to cutoff, and a positive square-wave signal is applied to them. In the positive half-cycles of the square wave, the voltage drop across the common cathode resistor should be sufficient to bring *V*1 to cutoff, with the maximum a-c signal applied.

Since the required square wave is of small amplitude, the output stage of the square-wave generator is made a cathode-follower circuit with a small output resistance. This modification makes the square-wave generator suitable for use at much higher frequencies. If it is considered, as mentioned before, that the upper limit of the value of *CRf* is 0.0565 at unity pf and 0.007 at zero pf, and taking *R* as 200 ohms and *C* about 10 micromicrofarads (for a high-frequency pentode in a cathode follower circuit), then the predicted higher limits of the frequency range will be in the neighborhood of 30 mc and 3.5 mc respectively. However, 30 mc seems to be a high value, especially as regards the operation of the square-wave generator (as other factors not considered will cause trouble at such a high frequency), and 10 mc can be considered as the probable higher limit.

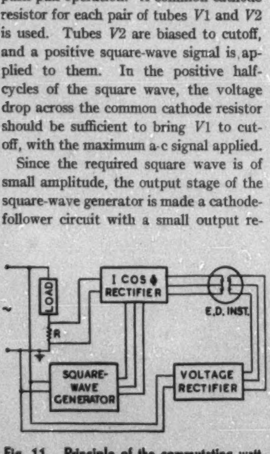

Fig. 11. Principle of the commutating wattmeter

As far as the different sources of error are concerned, this type of pf meter will behave the same as the other two types, and the errors will also be negligible.

Commutating Wattmeter

By means of any of the three aforementioned devices, a direct current proportional to *I* cos φ could be produced. If, now, the voltage across the load is rectified so that a d-c output proportional to the voltage is obtained, the product *VI* cos φ is most easily secured through the use of an ordinary electrodynamic instrument, and the whole arrangement takes the form shown in Fig. 11.

ELECTRODYNAMIC INSTRUMENT

The multiplication of the two d-c signals *I* cos φ and *V* can be effected electronically. However, since the two signals are already obtained in the form of direct currents, it is believed that an electrodynamic instrument would provide a simple and the most straightforward solution. Its design and manufacture would encounter no special difficulties, especially as regards sensitivity and accuracy.

A survey of a number of typical electrodynamic instruments of the laboratory type has shown that in order to obtain full-scale deflection, a relatively large power, of the order of a few hundred milliwatts, is required for the current as well as for the voltage coils.

It should be pointed out that some of the modern types of instruments have better sensitivity, and much more sensitive electrodynamic instruments could be obtained by abandoning the classical technique of using air-core instruments, and using iron-core instruments instead, and consequently a sensitivity as good as that of the moving-coil d-c instrument could be obtained. Iron has many defects, especially when used as a core for a coil carrying direct current to produce a magnetic flux. However, several papers[10-12] have described iron-core instruments which overcome these defects. In the present work, it was not possible to obtain or to construct such a new type of instrument, and therefore stress was given to obtaining as much power from the circuits as possible through the use of normal, powerful receiving-type tubes and comparatively large a-c signals, and sacrificing the use of acorn tubes to extend the working frequency range.

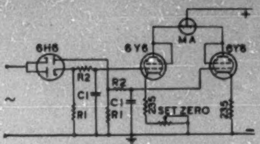

Fig. 12. The voltage rectifier

The usually available electrodynamic instruments have their coils designed for operation in ordinary power supply circuits, and will thus not be suitable for use in conjunction with the circuits under consideration. Therefore the coils of one of these instruments had to be rewound with the proper number of turns and wire diameter and to the proper value of their resistance, but at the same time having almost the same physical shape and size as the original coils. Moreover, the use of push-pull circuits necessitates that each coil should consist of two sections which should be electrically and physically identical, and therefore the bifilar construction was adopted.

The rewound moving coils of the instrument had 1,400 turns and about 1,500 ohms each, while the field coils had 4,000 turns and 900 ohms each. The instrument was provided with a uniform scale.

VOLTAGE RECTIFIER

The voltage rectifier circuit is shown in Fig. 12. A type-*6H6* tube is used for rec-

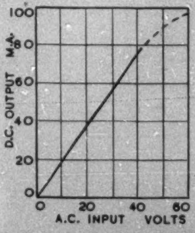

Fig. 13. Characteristic of the voltage rectifier

Vol.
Pt. 1
1955

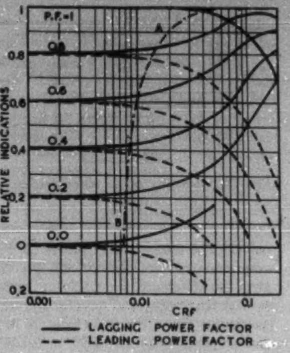

Fig. 14. Effect of stray capacities on meter readings (experimental)

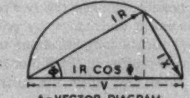
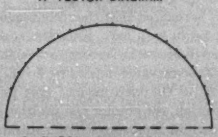
tification. The direct voltage appearing across capacitor *C1* will be equal to the peak value of the applied alternating voltage. If this voltage contains appreciable harmonics, it would be preferable to obtain the average value, which is less sensitive to harmonics, across *C*1. This can be effected through reducing *R*1 and increasing *R*2.

Two type-*6Y6* beam tetrodes, used as cathode followers, are operated in push-pull in order to eliminate errors resulting from nonlinearity that may exist in the working range of their characteristics. These tubes are chosen because of their large current ratings and large mutual conductances, in order to provide the large current necessary for the operation of the electrodynamic indicating instrument. The value of the cathode resistor was chosen with a view to obtaining as large a linear range of characteristic as possible, as maximum an output power as possible, and the linear part of the characteristic extending equally on both sides of the zero input voltage axis so that the tubes are operated without grid bias supply.

The circuit was tested for varying a-c input voltages, the results of which are given in Fig. 13, which shows good linearity from zero up to 45 volts a-c with these tubes. It is obvious that this range can be easily extended as desired by applying only a known fraction of the rectified voltage to the grids of the type-*6Y6* tubes.



A-VECTOR DIAGRAM



B- EXPERIMENTAL RESULTS

Fig. 15. Testing the I cos φ meter, using resistance-capacitance circuit

Experimental Verification

Each type of the pf meters was tested by comparing its readings with those of a dynamometer wattmeter at 50 cycles. Line voltage was applied to the voltage coils of the dynamometer wattmeter as well as to the input of the square-wave generator. This same voltage was made to supply current to a resistive load, and the phase angle of this current was varied by means of a phase shifter introduced between the supply and the load. The same current was passed through the current coils of the electrodynamic wattmeter, while a small fraction of the voltage across the resistive load was applied to the input of the pf meter. Tests were carried for different values of supply voltage, load current, a-c input signal, and for pf from unity to zero. In all cases, results showed close linear relation between the readings of the pf meter and the readings of the electrodynamic wattmeter (divided by the supply voltage). The accuracy as well as the sensitivity were quite satisfactory. Full-scale reading could be obtained by an a-c signal of only a small fraction of a volt, at unity pf, depending on the sensitivity of the indicating instrument. With the grid-controlled meter, an a-c signal of 0.2 volt gave a reading of 24 microamperes (μA) on a bridge-connected indicating instrument of 5,000-ohm resistance, and 43 μA on an instrument of 1,667-ohm resistance. With the suppressor-controlled meter, the same signal gave a reading of 720 μA when using the differential connection, and 300 μA when using a bridge-connected instrument of 1,200-ohm resistance. With the cathode-controlled meter, the same signal gave 120 μA on a bridge-connected 5,000-ohm instrument. The sensitivity can still be increased by using tubes of higher transfer characteristic slopes, or by using more sensitive indicating instruments.

The frequency characteristics of the pf meter, predicted in Fig. 8, were checked simply by increasing the value of *C* instead of increasing *f*, so as to be able to compare the readings to those of the electrodynamic wattmeter. Two similar decade capacitors were connected across the square-wave generator output. The readings obtained by the grid-controlled pf meter are shown in Fig. 14 for different pf. A large input signal (7.5 volts) was used. It is interesting to note that these curves agree quite well in shape and in magnitude with the curves of Fig. 8. The same test was repeated for different input signals, and the error was found to be almost independent of the signal amplitude.

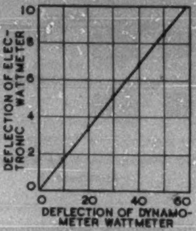


Fig. 16. Results of a test on the commutating wattmeter

Some tests were also carried out on the pf meters at frequencies other than the power-line frequency. In one of these tests an oscillator was connected to a simple series circuit consisting of a noninductive resistance and a calibrated decade capacitor. The frequency and output voltage of the oscillator were kept constant, while the capacitor was varied, and the meter was connected to give readings of *IR* cos φ and *IR*, from which *R*, *X* and cos φ were calculated, and the results plotted in vector form as shown in Fig. 15, which shows also the theoretical semicircle to be expected, for comparison. The figure shows close accuracy of the readings, as the error was always less than 1%. The fact that the experimental points tend to lie outside the circle indicates that this small error is mainly the result of stray capacities. Actually this test is a rather severe one, since a small error in the readings appears exaggerated on the vector diagram.

The tests on the complete wattmeter were carried out on lines similar to those done on the pf meters, i.e., by comparison to the readings of an ordinary electrodynamic wattmeter at power-line frequency. In each test, two of the three variable quantities, viz., alternating voltage to the pf meter, alternating voltage to the rectifier circuit, and pf, were kept constant, and the third varied over its full range. The pf was varied from unity down to zero. The instrument indications are plotted against the electrodynamic wattmeter readings in

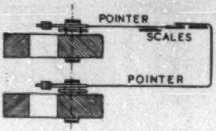

Fig. 17. Arrangement of the twin logarithmic instrument

Fig. 16, using the suppressor-controlled pf meter. The figure shows very good linearity and accuracy. As regards the sensitivity of the wattmeter, it is worth mentioning that, even by using the cumbersome and insensitive electrodynamic multiplying instrument which could be provided, it was possible to obtain full-scale deflection of the instrument by using a current signal of about 1 volt and a voltage signal of about 45 volts.

D-C Division Device

In the preceding sections were described circuits developed by means of which it is possible to measure the inphase component of current, i.e., the product $I \cos \varphi$. The value of the pf, $\cos \varphi$, can be obtained either by measuring the value of I (by the use of the same instrument) and dividing the two readings, or by setting the a-c input signal to the instrument to a predetermined value and calibrating the instrument to give a direct reading of $\cos \varphi$. In both cases, the pf meter can hardly be considered a direct-reading one.

A direct-reading instrument, giving $\cos \varphi$ rather than $I \cos \varphi$, would certainly be much preferable and more useful. Such an instrument would incorporate a device which is capable of dividing two quantities and giving a direct reading of the quotient. Since the quantity $\cos \varphi$ is obtained in the form of a direct current, it is necessary that the other quantity I also be converted to a direct current, and the required dividing device be essentially capable of dealing with d-c signals. A simple d-c division device is described in the following.

The device primarily makes use of the known mathematical relation, that the logarithm of the quotient of two quantities is equal to the difference between the logarithms of the two quantities. As the quantities concerned in this case are direct currents, their logarithmic functions can be simply obtained by the use of log-scale d-c instruments.

Log-scale indicating d-c instruments[13] have actually been designed and manufactured by mass-production technique, with no difficulties from scale distribution. Essentially it is a moving-coil d-c instrument with a magnetic structure of special design. In one case, a full-scale deflection has been obtained with a current of only 150 μA.

The scale of the instrument can be regarded as a part of a slide rule, with the pointer performing the computation. Imagine one scale on which two pointers move, beginning from the same zero point, one pointer deflection being a log function of a certain quantity P, and the other pointer deflection a log function (to the same base of the system of logarithms) of another quantity Q. The angle between the two pointers is then proportional to the logarithm of the quotient P/Q, and the number of scale divisions between the two pointers gives the quotient directly. That the instrument may be direct-reading, means should be available so that this number of scale divisions may be read directly. In other words, the zero reading should now be placed just at the position of one of the pointers, whatever this position may be. This at once suggests that the scale on which the readings are to be taken shall be movable, and fixed to the pointer at its zero-reading point. The other pointer moves on the same scale, and its position will directly give the difference displacement angle, so that its reading will directly give the quotient. Since the movement of the second pointer can be larger or smaller than that of the first, depending on whether the quotient is greater or less than 1, then the movable scale should extend on both sides of its zero-reading point. If the indications are to be read directly as quotients, the indication at this point should read 1. The right-hand side of the scale carries numbers greater than 1, while the left-hand side carries fractions.

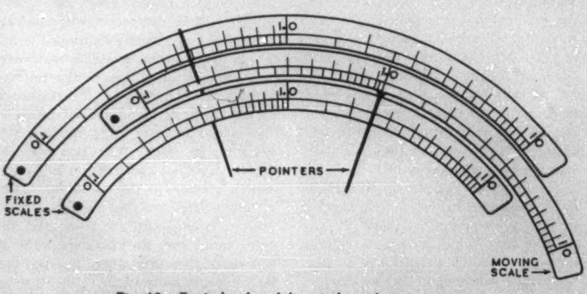

Fig. 18. Typical scales of the twin logarithmic instrument

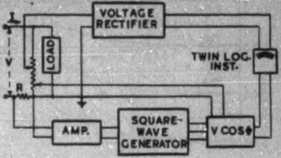

Fig. 19. Principle of the direct-reading pf meter

This principle can be easily effected by means of a twin instrument having two separate and identical log-scale movements. The arrangement of the instrument is shown in Fig. 17. The two movements are placed one above the other and adjusted such that they rotate about the same vertical axis, having the same point of beginning, and are then fixed firmly in their positions. The pointer of the upper movement carries the moving scale, which has to be as light and well balanced as possible, while the pointer of the bottom movement is bent so that it can read on the moving scale.

The twin instrument can be used to give readings of not only their quotient, but of the two quantities which are being divided, by providing each movement with a fixed log-scale. The arrangement of the three scales is shown in Fig. 18.

It is possible to make the two parts of the instrument multirange, by providing each coil with a variable shunt to vary the current passing in the coil in steps of known ratios, by which the instrument readings are to be multiplied.

It is realized that the scale readings do not begin with zero, since the scales are logarithmic. The readings would then begin at some value depending on the sensitivity of the instrument. Not to cause confusion, the pointer rest position (when no current is passing in the instrument) is preferably shifted a little to the left of the start of the scale readings. No readings should be taken when either pointer is in its blank region, in which case the sensitivity of the instrument has to be increased by varying its shunt.

The instrument will not give readings when a negative current passes in it, and therefore it has to be provided with a reversing switch, whose position will indicate whether the reading is to be considered positive or negative.

Finally, it is worth mentioning that the sensitivity of such an instrument would approximate the sensitivity of a conventional linear-scale d-c instrument, provided it would be taken into consideration that the log-scale instrument usually requires more power for equal full-scale rating. The accuracy of the instrument is of the same order as for the linear-scale instrument, or even better accuracy can be obtained in the lower half of the scale.

Direct-Reading PF Meter

The direct-reading pf meter consists of:

1. A commutating circuit to give the inphase component $V \cos \varphi$.
2. A voltage rectifier circuit.
3. A d-c dividing device.

The reason for obtaining $\cos \varphi$ through dividing $V \cos \varphi$ by V (and not dividing $I \cos \varphi$ by I) will be obvious if it is remembered that it is always an essential requirement for the signal obtained from the current element (by the insertion of a resistance in series with the circuit) to be as small as possible. When this small signal is rectified, the direct current obtained might be insufficient for the dividing instrument. Amplification of the signal would therefore be necessary. If the pf meter is to cover a wide frequency range, the amplifier has to be capable of providing a constant gain all over this range, which is not an easy matter, if it could be realized at all.

A direct current which is proportional to the product $V \cos \varphi$ can be obtained in the same manner as already explained for $I \cos \varphi$, i.e., by the use of a square-wave generator operated from the current signal, together with a commutating circuit for which the input is derived from the voltage circuit. An amplifier stage may then be required at the input to the square-wave generator, but this represents no difficulty, since its gain need not be constant, but it should give a negligible phase shift.

A block schematic diagram of the direct-reading pf meter is shown in Fig. 19. The two d-c outputs of the commutating circuit and the voltage rectifier are connected to the twin logarithmic instrument. The instrument then gives direct readings of $V \cos \varphi$, V, and $\cos \varphi$ simultaneously.

Applications of Instruments

It is to be gathered from the foregoing that one instrument can be used for the measurement of voltage, current, pf, or power. This can be readily accomplished through the addition of simple switching arrangements to switch over one or the other of the two a-c signals to the inputs of the square-wave generator, commutating circuit, or voltage rectifier, and to take readings either on a d-c instrument, an electrodynamic indicating instrument, or a twin logarithmic instrument.

The instrument may also be used as a multirange one. The a-c signal derived from the load-current circuit can be changed by making the series resistor vary in known steps. The a-c signal derived from the load-voltage circuit can be changed either by using a voltage divider to take known fractions of this voltage (though this introduces some loss and may cause some difficulties at the higher frequencies), or preferably by using a capacitor voltage divider circuit for the rectified output of the type-*6H6* tube in the voltage rectifying circuit. The instrument can also be used for impedance measurements under actual operating conditions of voltage and frequency. Finally, the instrument can be made as one self-contained a-c operated unit incorporating its power supply circuit.

Discussion

James E. Van Ness (Northwestern University, Evanston, Ill.): This a fine discussion on the use of a commutating circuit for determining components of voltage or current, and on the errors that can arise. I have used this type of circuit in a special-purpose computor with a network analyzer and have found it very satisfactory. The work has been described elsewhere.[1]

In my work, I used a slightly different type of circuit in order to avoid having a steady-state d-c current to balance out. As mentioned in the paper, if the push-pull type of circuit is not used, any variation in the power supply voltage will cause an error in the reading of the indicating meter. Even with the push-pull arrangement, any change in the emissions of the tubes, as from aging or change of heater voltage, will cause an error unless the change is identical in the two tubes. Therefore, difficulties of the type found in the design of d-c amplifiers are likely to occur. I wonder if it would not be well to provide a simple calibrating circuit with this type of instrument for use in zeroing the meter.

For lower frequencies a very simple instrument could be built using a chopper of the type commonly found in servo amplifiers. The chopper could be driven directly by the voltage signal, and the current applied to a d-c meter through the chopper contacts. While the arrangement is not as flexible as one using electronic tubes, it is relatively simple and would avoid any difficulties arising from a steady-state d-c component.

There is one possible source of error in the wattmeter proposed in this paper which I feel should be pointed out. If the rectified voltage signal is not well filtered, the harmonics in its output will react with the harmonics in the output of the commutating circuit and change the reading of the meter. As the harmonic content of the commutated signal can often be much larger than its d-c component, this could be serious. Therefore, the voltage rectifier must include adequate filtering of the signal.

REFERENCE

1. SYNCHRONOUS MACHINE ANALOGUES FOR USE WITH THE NETWORK ANALYZER, James E. Van Ness. *AIEE Transactions*, vol. 73, pt. III, Oct. 1954, pp. 1054–60.

M. Abdel-Halim Ahmed: Mr. Van Ness refers to a simple instrument using a chopper. I have used a similar device for many years in measuring the errors of instrument transformers. The device consisted essentially of a synchronous electromechanical vibrator. It is obvious that such an instrument is suitable only at power frequencies, and has to be retuned whenever the frequency is varied. The troubles which usually arise when vibrating contacts are used are obvious.

To avoid having a steady-state direct current to balance out (although, as will be seen, this does not represent any difficulty) it might be possible to replace the tubes by metal rectifiers, as is usual with modulators used in carrier-current telephone work. This arrangement is still not as flexible and has not as wide a frequency range as one using electronic tubes, but it is definitely much superior to an electromechanical device.

Mr. Van Ness points out that errors may arise from supply voltage variations and changes in the emissions of the tubes when the change is not identical in both tubes, and asks for a calibrating circuit for zeroing the meter. These errors may be either zero-reading errors or errors in the reading of the instrument. With the cathode feedback type of circuit adopted, the equation

S = slope of the transfer characteristic of either tube

$$=\frac{\text{cathode current}}{\text{grid voltage}}=\frac{\mu}{\mu+1}\,\frac{1}{R_k+\dfrac{\rho+R_a}{\mu+1}}$$

shows that the tube current is almost independent of the tube parameters μ and ρ, since the fraction $\mu/(\mu+1)$ is almost equal to unity and $(\rho+Ra)/(\mu+1)$ is made much smaller than R_k. The tube current, as well as the value of S are therefore determined by the value of the cathode resistor R_k. This value is adjusted to be equal for both tubes by the small variable resistance added in the cathode circuit of one of the tubes, as shown in Figs. 3, 9, and 10. The adjustment of this resistance for zero no-signal current in the indicating instrument will also make the transfer characteristics of both tubes identical. In this case, trouble with the zero reading is entirely eliminated, and the error in the instrument reading due to supply voltage variations, aging or replacement of the tubes, etc., is reduced to a negligible amount.

However, the instrument can always be readily calibrated by switching it to read either current or voltage, and comparing its reading with that of an ordinary ammeter or voltmeter, and there will be no need to add a special calibrating circuit. If any error is noted, this will only involve multiplying the instrument reading by a constant factor.

I agree that for using the instrument as a wattmeter, the rectified voltage signal has to be well filtered. The voltage rectifier circuit takes care of this. However, as mentioned in the paper although not shown in the figures, the indicating instrument in the commutating circuits may be conveniently shunted with a capacitor to by-pass the alternating components in the output of the commutating circuit; and the same procedure can be followed with the voltage rectifier circuit. No error in the wattmeter reading will result in this case.

Theory of Magnetic Cross Valves

W. H. HIGA
NONMEMBER AIEE

A PHYSICAL and mathematical theory of the interaction of two mutually orthogonal coils in a ferromagnetic medium is developed. For purposes of analysis, an idealized configuration with cross-sectional view, as shown in Fig. 1, is studied. Two coils, x and y, are wound at right angles to each other about a cylinder of ferromagnetic material of permeability μ. The structure is then immersed in a medium of infinite permeability. This last requirement is not stringent, it being required only that the saturation effects be confined to the central core for purposes of analysis. It is assumed further that the core material has no hysteresis or eddy-current losses while its typically nonlinear magnetization curve is as shown in Fig. 2. It is shown how the nonlinearity in the magnetization curve results in the interaction of the orthogonal circuits.

A practical version of the configuration under analysis was first described by H. J. McCreary who has made many interesting applications of the device.[1] The primary importance of the magnetic cross valve is in frequency-changing applications. Large amounts of power can be supplied at one-half or one-third line frequency.

The nature of nonlinear coupling is such that there must exist, initially, a field component orthogonal to the applied modulating field. It is shown that, in the absence of the orthogonal field, there can be no interaction. Although, in the first example, a constant orthogonal field is used, it is also possible to have a periodically varying field modulated by the applied one. This type of operation requires a capacitor in the secondary circuit. An oscillatory state may then be established and maintained in the secondary circuit. This phenomenon is closely related to ferroresonance in other types of circuits containing iron-cored inductors and capacitors.[2] The importance of ferroresonance lies in the fact that the sustained oscillations may be at a multiple or submultiple of the driving generator frequency.

Physical Analysis

To explain the physical mechanism through which interaction can occur in orthogonal circuits, it will be convenient to assume that the magnetic medium is homogeneous and isotropic. Quantities are defined as follows:

H_x = magnetic field caused by coil x
H_y = magnetic field caused by coil y
φ_x = flux-threading coil x
φ_y = flux-threading coil y
$\mathbf{H}$ = field vector with components H_x and H_y; $H=|\mathbf{H}|$
$\boldsymbol{\varphi}$ = flux vector with components φ_x and φ_y; $\varphi=|\boldsymbol{\varphi}|$
$\dot{\varphi}=d\varphi/dt$
$\ddot{\varphi}=d^2\varphi/dt^2$

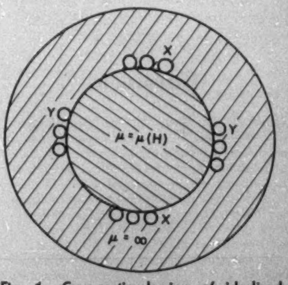

Fig. 1. Cross-sectional view of idealized magnetic cross valve

Paper 55-8, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted March 18, 1954; made available for printing October 27, 1954.

W. H. HIGA is with the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, Calif., and was with North American Aviation, Inc., Downey, Calif., when the paper was prepared.

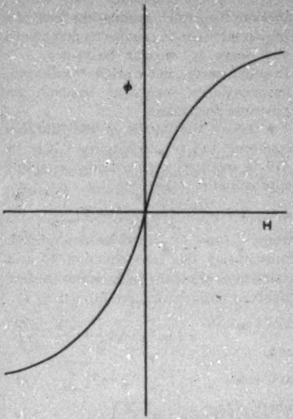

Fig. 2. Magnetization curve for core of Fig. 1

Fig. 3 shows a typical plot of the loci for the **H** and φ. Here it is assumed that H_x is held constant and H_y is varied; furthermore, the permeability is assumed to be constant. It can be seen readily that in the case of constant permeability, the loci for **H** and φ can be brought into coincidence by a proper choice of scale factor, There if, of course, no interaction in this case.

Fig. 4 shows the loci for **H** and φ when the nonlinearity of the core material is taken into account. In particular, a constant field component H_x is assumed and H_y is varied. If the component H_x is sufficiently large, there will be little change in the length of φ with changes in H_y; however, φ will always be parallel to **H**. Thus, it can be seen that the loci for **H** and φ cannot be brought into coincidence here. A study of Fig. 4 shows that a variation in H_y causes a variation in the component φ_x. Thus, if H_y varies periodically with time, there results a periodic variation φ_x in which induces an electromotive force in coil x. Fig. 5 shows a plot of H_y and φ_x as functions of time. It is apparent that the variations in φ_x occur at twice the frequency of the variations of H_y. Thus, a frequency doubler is easily obtained through the connections shown in Fig. 6.

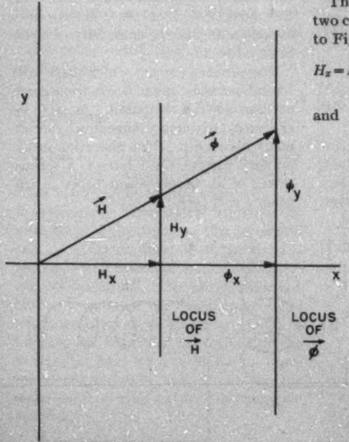

Fig. 3 (left). Loci for H and φ when μ=constant

Mathematical Analyses

The basic assumption in this study is that the phenomena associated with the magnetic cross valve are phenomena on the macroscopic scale. That it to say, it is assumed that the total flux vector φ and an average field vector **H** are adequate in deducing a theory. The actual distribution of the field in the core need not be discussed. This assumption was, of course, made in the foregoing.

The nonlinear magnetization curve of Fig. 2 may be expressed analytically as

$$H=a\varphi+b\varphi^3+c\varphi^5+\ldots \tag{1}$$

where the coefficients a, b, c, etc., are obtained from the curve. It will be adequate here to drop all but the first two terms. Hence, the basic equation is

$$H=(a+b\varphi^2)\varphi \tag{2}$$

The components associated with the two coils are readily obtained by referring to Fig. 4 and are

$$H_x=H\cos\theta=H(\varphi_x/\varphi)=a\varphi_x+b(\varphi_x^2+\varphi_y^2)\varphi_x \tag{3A}$$

and

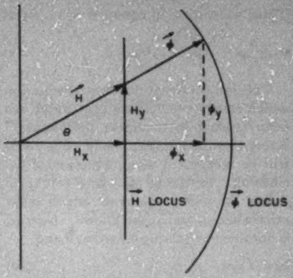

Fig. 4. Loci for H and φ when $\mu=\mu(H)$

$$H_y=H\sin\theta=H(\varphi_y/\varphi)=a\varphi_y+b(\varphi_x^2+\varphi_y^2)\varphi_y \tag{3B}$$

Before deducing from equations 3, the basic equations of ferroresonance, it will be convenient to normalize the quantities H_x, H_y, φ_x, φ_y as follows

$$H_x=ki_x=i_x \tag{4A}$$

$$H_y=ki_y=i_y \tag{4B}$$

and

$$\varphi_x=Ke_x=e_x \tag{5A}$$

$$\varphi_y=Ke_y=e_y \tag{5B}$$

The same number of turns in the primary coil y and the secondary coil x are assumed, and constants of proportionality k and K are assumed equal to unity. Thus, equations 3 can be written as

$$i_x=a\varphi_x+b(\varphi_x^2+\varphi_y^2)\varphi_x \tag{6A}$$

$$i_y=a\varphi_y+b(\varphi_x^2+\varphi_y^2)\varphi_y \tag{6B}$$

Consider now the circuit shown in Fig. 7; the secondary current is found from

$$\varphi_x+\frac{\int i_x dt}{C}=0 \tag{7}$$

or

$$i_x=-C\dot{\varphi}_x \tag{8}$$

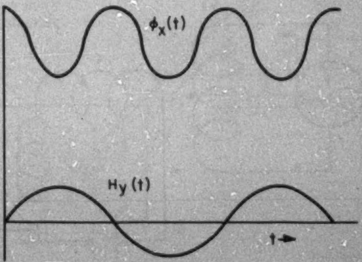

Fig. 5 (right). Variations of $H_y(t)$ and $\varphi_x(t)$ as functions of time

l, 74
1
55

Thus, substution in equation 6(A) yields

$$\ddot{\varphi}_x+\frac{a}{C}\varphi_x+\frac{b}{C}(\varphi_x^2+\varphi_y^2)\varphi_x=0 \tag{9}$$

This is a nonlinear differential equation which closely resembles a type which has been studied in nonlinear mechanics.[3,4] Except for the nonlinear term, equation 9 will be recognized as an equation of oscillation. Equation 6(B) now serves to define the primary current which must exist when φ_x and φ_y are known. Now φ_x is obtained by solving equation 9 and

$$\varphi_y=\int e_y dt \tag{10}$$

To find particular solutions to equation 9 is the next step. It should be pointed out that most nonlinear differential equations do not have general solutions as is the case with linear ones. The equation must be solved for each new set of conditions. This will be illustrated by the examples that follow.

CASE I: THE PHASE-SHIFTING TRANSFORMER

Let $e_y=E_0 \sin \omega t$ be the voltage applied to the primary winding and let $\varphi^2=\varphi_x^2+\varphi_y^2=\Phi_0^2$ (a constant).

Here

$$\varphi_y=-\frac{E_0}{\omega}\cos \omega t=-\Phi_0 \cos \omega t$$

and

$$\varphi_x=\frac{E_0}{\omega}\sin \omega t=\Phi_0 \sin \omega t \tag{11}$$

to satisfy the second condition. Substituting in equation 9

$$-E_0\omega+\frac{a}{C}\frac{E_0}{\omega}+\frac{b}{C}\left(\frac{E_0}{\omega}\right)^3=0 \tag{12}$$

or

$$C=\frac{1}{\omega^2}\left(a+b\frac{E_0^2}{\omega}\right) \tag{13}$$

This results states that if a voltage $E_0 \sin \omega t$ is applied to the primary, a voltage

$$e_x=\dot{\varphi}_x=E_0 \cos \omega t \tag{14}$$

will appear across the secondary, provided that the relation of equation 13 is satisfied and that an initiating transient is introduced in the secondary. The last condition is necessary since interaction cannot occur in the absence of an orthogonal field.

In practice, the condition specified by equation 13 is not as critical as it may first appear. The reason for this is that the constant a and b actually depend on the operating range on the magnetization curve. Hence, when at least close to the proper range, it is possible for the circuit to adjust itself to satisfy equation 13.

It is, in fact, this flexibility in the circuit which permits at least a little power from the secondary circuit to be drawn. When the resistive load becomes too large, the circuit will abruptly stop oscillating. These matters are concerned with stability criteria in ferroresonance and are not discussed here.

CASE II: GENERATION OF SUBHARMONIC OF ORDER ONE-HALF

Let

$$\varphi_y=\Phi_0+\frac{E_0}{\omega}\cos \omega t$$

with

$$\Phi_0>>\varphi_x \text{ or } \varphi_y$$

then equation 9 becomes

$$\ddot{\varphi}_x+\frac{a}{C}\varphi_x+\frac{b}{C}\left[\Phi_0^2+2\Phi_0\frac{E_0}{\omega}\cos \omega t\right]\varphi_x=0 \tag{15}$$

This equation may be written as

$$\ddot{\varphi}_x+(\alpha+2\beta \cos \omega t)\varphi_x=0 \tag{16}$$

where

$$\alpha=\frac{a}{C}+\frac{b}{C}\Phi_0^2 \tag{17}$$

and

$$\beta=\frac{bE_0\Phi_0}{C\omega} \tag{18}$$

Equation 16 is the Mathieu equation which has the interesting feature that, when α and β satisfy certain conditions, periodic solutions obtain. Moreover, this solution which assumes the form of a trigonometric series has for its first term a sine wave of angular frequency $\omega/2$. In other words, under proper conditions, ferroresonance occurs at one-half the generator frequency.

Although the details of the Mathieu equation[5] will not be discussed here, it will be instructive to consider a simple approximation. Let

$$\varphi_x=\lambda_1 \cos(\omega t/2)+\lambda_2 \cos(3\omega t/2) \tag{19}$$

where λ_1 and λ_2 are to be determined. Substituting this into equation 16 and equating coefficients of like terms in time yields

$$a_{11}\lambda_1+a_{12}\lambda_2=0 \tag{20}$$

and

$$a_{21}\lambda_1+a_{22}\lambda_2=0 \tag{21}$$

where

$$a_{11}=\frac{1}{C}\left(a+b\Phi_0^2+\frac{bE_0\Phi_0}{\omega}\right)-\frac{\omega^2}{4}$$

$$a_{12}=a_{21}=\frac{bE_0\Phi_0}{C\omega}$$

and

$$a_{22}=\frac{1}{C}(a+b\Phi_0^2)-\frac{9\omega^2}{4}$$

Equations 20 and 21 can yield unambiguous solutions for λ_1 and λ_2 only if

$$\begin{vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{vmatrix}=0 \tag{22}$$

Thus, there is again a condition on the circuit parameters which must be satisfied for subharmonic resonance. In obtaining equations 20 and 21, a term ($\cos 5\omega t/2$) has actually been discarded; this must be done unless it is desired to assume more exactly an infinity of terms in equation 19.

The primary current which must exist for subharmonic resonance in the secondary can now be computed. As is to be expected, the primary current will contain many harmonics. This distortion in the primary current wave form is a serious defect of all ferroresonant types of frequency changers.

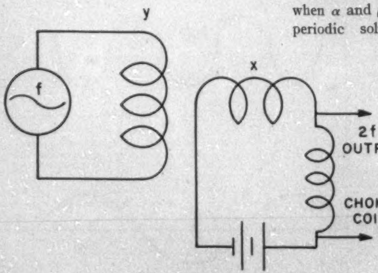

Fig. 6 (left). Simple frequency doubler

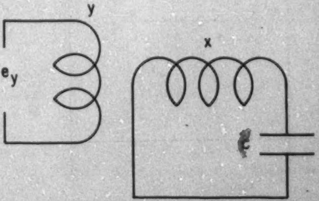
Fig. 7 (right). Ferroresonant transformer



Vol. 7
Pt. 1
1955

CASE III: GENERATION OF SUBHARMONICS OF ORDER ONE-THIRD

Let

$$\varphi_y = \Phi_y \sin \omega t$$

and

$$\varphi^3 \neq \text{constant}$$

Here, a generalized problem of which case I was a specialization is being considered. Accordingly

$$\varphi_x = \sum_{n=1}^{\infty} \Phi_{n/k} \sin \frac{n\omega t}{k} \qquad (23)$$

where k is an integer. Substitution of φ_x in to the differential equation leads to

$$\left(\frac{a}{C} - \frac{n^2\omega^2}{k^2} + \frac{b}{C}\Phi_y^2 \sin^2 \omega t\right) \times \sum \Phi_{n/k} \sin \frac{n\omega t}{k} + \left(\sum \Phi_{n/k} \sin \frac{n\omega t}{k}\right)^3 = 0 \qquad (24)$$

The coefficients Φ will have nontrivial solutions only if there are common time factors in the first and second terms of equation 24. Hence, in view of the identity

$$\sin 3\theta = 3 \sin \theta - 4 \sin^3 \theta$$

and the occurrence of the cubed term in equation 24, the following approximate solution can be justified

$$\varphi_x = \Phi_{1/3} \sin \frac{\omega t}{3} + \Phi_1 \sin \omega t \qquad (25)$$

When this solution is substituted into the differential equation, two equations are obtained for the solution of the Φ_s'. As in the previous cases, the circuit parameters must satisfy certain relations in order that ferroresonance of order one-third occurs. The details, unfortunately, are cumbersome with algebra and will be omitted here.

Conclusions

It has been shown that the mechanism of frequency changing in the magnetic cross valve can be readily analyzed. Although many simplifying assumptions were made in the course of this investigation, it appears that all of the experimental observations of H. J. McCreary[1] can be explained. The use of only the first two terms in the expansion for the magnetization curve has the effect of limiting the harmonic distortion for the modes that have been considered. More terms are required to account for the many more complex modes of operation possible.

The differential equation 9 which governs the ferroresonance phenomena is related to the equation of Duffing which has been studied extensively in nonlinear mechanics.[3,4] The inclusion of dissipative currents in the system adds a first time derivative term $\dot{\varphi}$ to equation 9. The principal effect of such a term would be to introduce phase shift into the voltages and currents.

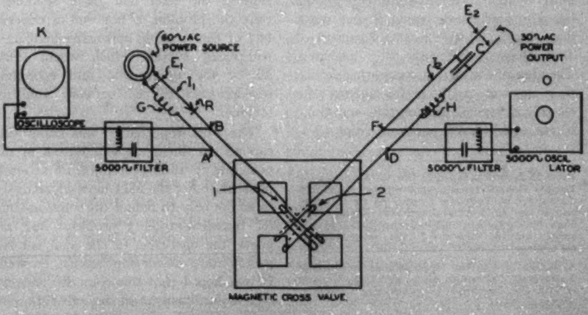
◆

Discussion

Harold J. McCreary (Automatic Electric Company, Chicago, Ill.): This is a very commendable contribution to the literature concerning the magnetic cross valve. While, as the author states, many simplifying assumptions were made, nevertheless he arrives at the Mathieu equation as a solution representing what takes place in the magnetic cross valve. This also appears to be Edson's conclusion in his book *Vacuum Tube Oscillators*.[1]

Since the apparent object of the paper is to clarify by means of mathematics, what takes place in the magnetic cross valve, and why, perhaps I can appropriately add some experimental evidence on the reasons for what takes place. (The process itself was covered fairly well by oscillograms in my article, "The Magnetic Cross Valve," see reference 1 of the paper).

Fig. 8. Auxiliary test equipment



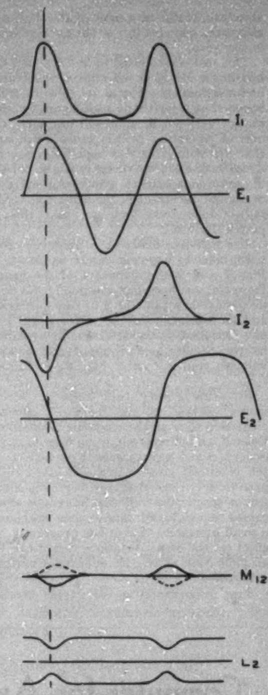


Fig. 9. Oscillograms of input and output voltage and currents

MUTUAL INDUCTANCE

The results can obviously be attributed to the peculiar relationship between the input coil and output coil. This relationship is usually called "mutual inductance" and is assumed to be a constant. In the magnetic cross valve, because of its unusual structure, this is zero most of the time, and alternates periodically; so the average value is also zero.

This test was devised to indicate how the instantaneous value of mutual inductance and self-inductance varies. This test assumes that a relatively high-frequency current of very small value will not affect the normal operation of the cross valve and that the voltage of this high frequency induced in one coil is a direct indication of the instantaneous mutual inductance and rate of change of current in the other coil. The independent tests indicate that this is practically true.

The test was made on a magnetic cross valve used as a power ringer as shown in Figs. 7 and 9 of reference 1 of the paper. However, auxiliary test equipment was connected as shown in Fig. 8 of this discussion and the operation of the power ringer was not disturbed by the attachments as shown by the oscillograms of input and output voltages and currents, Fig. 9, I_1 E_1 and I_2E_2.

By using a very high frequency alternating current, it can be independently channeled through the magnetic cross valve, isolated, and filtered out, using filtering components which have practically no effect on the magnetic cross valve and its normal operation. Also, with such high frequency the magnetization of the magnetic core caused by this high frequency can be of such a small increment that it has practically no effect on the core saturation; yet it can be an indication of the instantaneous mutual inductance.

An oscillator which delivers 5,000 cycles is connected through a 5,000-cycle-per-second filter to the magnetic cross valve coil designated 2, imposing a high frequency on this coil.

Across the coil designated 1 of the magnetic cross valve, oscilloscope K is connected through a filter which passes only the 5,000 cycles. The oscillograph envelope M_{12} is what the oscilloscope K indicated.

The mutual inductance as indicated by the oscillogram envelope is zero most of the time, but shows up by allowing spurts of the 5,000 cycle to pass from coil 2 to coil 1 for very short intervals.

The mutual inductance occurs when the current in both coil 1 and coil 2 are a maximum. Successive couplings by mutual inductance are reversed relative to each other.

Self Inductance

Inductance is always measured by its effect on changing current. In fact, since R is constant for all practical purposes we may use the reactive voltage to indicate the value of X and of L, since X is proportional to L.

I feel therefore that this test indicates how the self-inductance of the magnetic cross valve is changing without seriously modifying the magnetic cross valve action.

An oscillator which delivers 5,000 cycles is connected through a filter to the magnetic cross valve coil designated 2, at F D, imposing a high frequency on this coil. To these same points F and D an oscillograph like K is connected through a filter which passes the 5,000 cycles only. The oscillograph envelope L_2 is what the oscilloscope indicated.

The impedance of the secondary coil as indicated by the envelope oscillogram L_2 is practically a straight line except at the time that mutual inductance comes into effect, throwing the primary and secondary circuits in parallel, and so decreasing the impedance. It can therefore be assumed that the self-inductance is a constant except for the time period when mutual inductance becomes effective.

I conclude that the self-inductance of coil 2 is a constant as shown by the oscillograph envelope L_2 and that the total reactive component of coil 2 is modified principally by the mutual inductance becoming effective and, in effect, connecting the primary circuit in shunt with the secondary circuit.

These tests substantiate our previous theories of how the magnetic cross valve works. In particular, as described in Fig. 2 of reference 1 of the paper.

P. N. HELLER
ASSOCIATE MEMBER AIEE

THE recent activity and interest in the development of computer methods for speeding up the solution time for power-system transient-stability problems has prompted the reporting of some work done on the Massachusetts Institute of Technology (MIT) network analyzer. The idea of coupling a computing device to a network analyzer for solving the electromechanical differential equations of the synchronous machine rotor positions following a fault or other large disturbances to the system is certainly not a new one. Many people have considered the idea and have concluded that the problem is not one of concept but of constructing and instrumenting a computing system which would fulfill all of the operational and economic requirements of the network analyzer service.

The work reported in this paper was carried out during an exploration of the possibility of adding computer units to each phase shifter of the MIT network analyzer so as not only to reduce the solution time for transient-stability problems but improve the operation of the analyzer for steady-state power-flow studies as well. It was hoped that this computer system would facilitate work on other power-system problems which heretofore were not undertaken because of computational difficulties.

The Power-System Problem

The solution of a power-system transient-stability problem requires the determination of the rotor angle of each machine or group of machines in the system as a function of time following the initiating disturbance. The rotor angle of a given machine, e.g., the kth machine in an n-machine system, is generally obtained from the following approximate equation which has been derived in the Appendix

$$\delta_k=\delta_k(0)+\omega_k(0)t+\frac{1}{M_k}\int_0^t\int_0^t(P_{ik}-P_{ok})dtdt \tag{1}$$

where

δ_k = the phase angle of the voltage behind the transient reactance of the kth machine

$\delta_k(0)$ and $\omega_k(0)$ = the initial value of δ_k and its initial rate of change respectively

M_k = the inertia constant of the kth machine

P_{ik} = the mechanical power supplied to the kth machine by its prime mover

---

Paper 55-5, recommended by the AIEE Computing Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31-February 4, 1955. Manuscript submitted September 7, 1954; made available for printing October 27, 1954.

A. Kusko is with the Massachusetts Institute of Technology, Cambridge, Mass., and P. N. Heller is with the Raytheon Manufacturing Company, Waltham, Mass.

The electric power output P_{ok} of the kth machine is given by

$$P_{ok}=\frac{E_k^2}{Z_{kk}}\cos\theta_{kk}-\sum_{j=1}^{n}\frac{E_kE_j}{Z_{kj}}\cos(\delta_k-\delta_j+\theta_{kj}) \qquad (2)$$

where

$j=1, 2, 3 \ldots k-1, k+1 \ldots n-1, n;\ j\neq k$
$E_k\underline{|\delta_k}$ = the voltage behind the transient reactance of the kth machine
$E_j\underline{|\delta_j}$ = the voltage behind the transient reactance of the jth machine
$Z_{kk}\underline{|\theta_{kk}}$ = the driving-point impedance from the kth machine to the system including the transient reactance of the machine
$Z_{kj}\underline{|\theta_{kj}}$ = the transfer impedance from the kth machine to the jth machine in the system including the transient reactances of the machines

Substitution of equation 2 into equation 1 yields

$$\delta_k=\delta_k(0)+\omega_k(0)t+\frac{1}{M_k}\int_0^t\int_0^t\left(P_{ik}-\frac{E_k^2}{Z_{kk}}\cos\theta_{kk}+\sum_{j=1}^{n}\frac{E_kE_j}{Z_{kj}}\cos(\delta_k-\delta_j+\theta_{kj})\right)dtdt \qquad (3)$$

Similar equations must be written for the remaining $(n-1)$ synchronous machines in the system and the resulting set of n simultaneous differential equations must then be solved. However, since a mathematical solution in closed form exists only in exceptional cases, methods other than those of formal mathematical analysis must be used.

Previous Work

Nearly all multimachine transient-stability problems presently are solved on network analyzers using the step-by-step method. The tediousness and inaccuracy of this method has led to a search for suitable machine methods for solving problems of this type. There have been a number of published accounts of successful designs of computers for this purpose, but no data on the installation and continued use of such computers in daily service have been provided. These computers fall into several categories which will be reviewed here.

In the first of these categories are the large-scale general-purpose analogue or digital computers which are theoretically capable of solving representative multimachine transient-stability problems. However, the transfer impedances and prefault conditions must be obtained first from a network analyzer or by manual calculation and then set on the computer. This requires sufficient time so that, despite the speed and ease with which the actual computation can be carried out, not much is gained by the use of a separate computer for routine multimachine transient-stability studies. A differential analyzer has been used for special work by Concordia and others.[1-3] A synchronous machine was represented in detail to study the effect of the excitation system of this machine and its prime-mover governor on the transient stability of a 2-machine system. An electric analogue computer operating on the same principle has been developed by Boast and Rector.[4] The mechanical parameters of the synchronous machines are represented in this computer by resistors and inductors; transfer admittances of the power system are represented by d-c amplifiers and photoformers. A conventional electronic analogue computer can be used in about the same manner. To solve an n-machine problem by either of these methods, $n(n-1)$ amplifiers and at least 1/2 $n(n-1)$ function generators are required to represent the transfer admittances.[4] Thus, 30 amplifiers and at least 15 function generators are needed for the solution of the electric part of a 6-machine problem.

Another class of computer[5] makes use of small synchronous machines and a 3-phase model representation of the power system under consideration. The d-c motor-driven synchronous machine sets are equipped with voltage and speed regulators, interchangeable rotors, and provisions for changing the field time constant of each machine by means of a feedback network so that both the static and the dynamic characteristics of the machine-prime mover sets in the actual system can be duplicated. Faults are applied cyclically and the resultant disturbance is recorded by means of a cathode-ray oscilloscope. The use of interchangeable rotors in this computer permits the study of the effects of rotor saliency and amortisseur windings, while the 3-phase representation of the power system makes it possible to study the effect of unsymmetrical faults and single-phase switching without resorting to sequence networks. In use, the model system will behave like a real power system and the usual problems of frequency control, load division, and voltage regulation will make its adjustment somewhat difficult.

The third class of computer stems from the original suggestion by Kimbark[6] in 1938 for coupling an analogue computer to a network analyzer and has the sound basis that the network analyzer actually solves the electric part of the electromechanical differential equations while the computer solves the mechanical part. Moreover, the power system representation on the network analyzer for transient-stability studies is practically the same as the representation used for the study of steady-state power flow; the transition from steady-state to transient analysis and back can therefore be made with little disruption. The all-electronic computers, described by Kaneff[7] and Shen and Lissner[8] for use with 10-kc network analyzers, are of this type; each computer unit and phase shifter comprises a single assembly. Van Ness[9] described a similar more elaborate system but gives limited construction details. For network analyzers operating at conventional frequencies Bekey and Schott[10] proposed a computer system in which the components of a mechanical differential analyzer are used to control the rotor position of each existing phase shifter. The use of human operators to read each wattmeter and feed data to the differential analyzer solves the power-sensing problem, although automatic methods are mentioned.

Experimental Computer Unit

A computer system similar in concept to the third class described in the foregoing was designed to work with the MIT network analyzer and an experimental computer unit for such a system was built and tested. This unit positions one phase shifter of the network analyzer in accordance with the solution of the power-system electromechanical differential equation. For a complete installation one such computer unit is required for each phase shifter used in the power-system representation.

The block diagram of the experimental unit is shown in Fig. 1. Watt-hour meter no. 1 is a 2-element watt-hour meter; one element measures the output energy of the phase shifter and the other element measures energy proportional to the mechanical energy supplied to the machine represented by the phase shifter. The number of revolutions made by the watt-hour meter disk, therefore, is proportional to the time integral of $(P_{ik}-P_{ok})$. A photoelectric pickup servomechanism positions a variac so that the variac output voltage V is proportional to the number of revolutions of the watt-hour meter disk. Thus

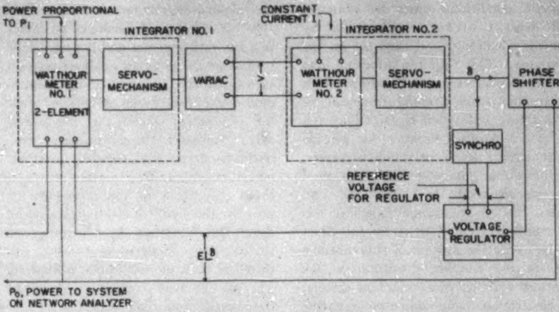

Fig. 1. Block diagram of the experimental computer unit

$$V = V(0) + K_1 \int_0^t (P_{ik} - P_{0k})dt \tag{4}$$

where

V = the output voltage of the variac
$V(0)$ = the initial value of that voltage
K_1 = a constant

The second integration is performed by the single-element watt-hour meter no. 2. One coil of this meter is connected to the output terminals of the variac and the other coil is supplied with a constant current I. Since the phase angle between this constant current I and the variac voltage V is fixed, the disk speed of the watt-hour meter no. 2 is proportional to the product IV, and the change in disk position is proportional to the time integral of IV. The rotor of the phase shifter is positioned by a photoelectric pickup servomechanism so that the angle through which the rotor turns is proportional to the number of revolutions made by the watt-hour meter disk. It follows that

$$\delta = \delta(0) + K_2 I \int_0^t V dt \tag{5}$$

where

δ = the mechanical angle of the phase-shifter rotor
$\delta(0)$ = the initial value of δ
K_2 = a constant
I = the constant current

Combining equations 4 and 5 yields

$$\delta = \delta(0) + K_2 I V(0)t + K_1 K_2 I \int_0^t \int_0^t (P_{ik} - P_{0k}) dt dt \tag{6}$$

By assigning proper values to the constants K_1, K_2, and I in equation 6 for the computer unit, this equation can be made analogous to equation 1 for the system. The solution of equation 2, the power-flow equation, is obtained from the network analyzer and the combination of analyzer and computer unit will, therefore, solve the complete electromechanical differential equation for one machine.

The voltage regulator, shown in Fig. 1, continuously corrects for the internal-impedance drop of the phase shifter in such a manner that the output voltage E of the combination of phase shifter and voltage regulator is constant in magnitude and that the phase angle of this voltage is equal to the computed value δ. The reference voltage for the voltage regulator is obtained from the rotor of a synchro which is coupled through an antibacklash gear train to the output shaft of integrator no. 2. The stator of this synchro is supplied from a source of constant 3-phase voltage. Since the output voltage of the phase shifter itself is nearly equal to the desired value, the voltage regulator need only furnish the small voltage necessary to correct for the internal-impedance drops. An electronic amplifier is used in the regulator of the experimental computer unit but other schemes may be used in permanent installations.

Fig. 2 shows the watt-hour meter of integrator no. 2 with the follow-up elements of the servomechanism. The meter itself is a standard 15-ampere 115-volt 60-cycle-per-second watt-hour meter; the current coil is supplied by a 6.3-volt 50-ampere transformer. Part of the phase shifter which is positioned by the computer unit is shown on the left of the watt-hour meter. This phase shifter, one of the regular units of the MIT network analyzer, is used with only very minor mechanical modifications.

Solution of Sample Problems

Two sample problems were run to test the experimental computer unit. The first test problem was the prediction of the power-angle excursion of a synchronous machine suddenly connected out of phase to an infinite bus. For certain initial conditions, there is a mathematical solution in the form of tabulated eliptic integrals. This solution was used as a convenient means of checking the computer accuracy. After 1 hour of computer operation corresponding to 6 seconds of system time, the amplitude of machine oscillation as given by the computer differed by less than 12 per cent from that computed from the mathematical equation. Some of the sources of this error are known and can probably be eliminated.

The second sample problem was the prediction of the power-angle transient for a single machine following a 3-phase fault and circuit-breaker operation in the transmission network connecting the machine to an infinite bus. The system, shown in Fig 3, was set up on the network analyzer and the power-angle excursions as a function of time were obtained from the computer unit for 3-cycle, 6-cycle, and 9-cycle clearing and variations thereof. Results are shown in Fig. 4. A time scale of 10 minutes of computer operation per second of system time made it possible to switch the fault and line connections on the analyzer manually without stopping the computation.

Use of the Computer Unit as a Power Regulator

Steady-state power-flow studies constitute the major portion of the work done on network analyzers. If the computer units of a permanent installation can be used to control the power output and out-

put voltage of the phase shifters in the analyzer, a saving in the time required to adjust the phase shifters can be realized. This can be done by increasing the computing speed of the computer units and providing some damping so that each phase shifter is moved rapidly to the position required for the desired power output. Control of the phase-shifter output power can however be achieved more simply if the mechanical connections are changed so that the rotor of the phase shifter and the reference synchro are driven by the output shaft of integrator no. 1. Preliminary tests of this second scheme indicated that this method is feasible but that some design problems remain to be solved.

Problems of Computer Design

It becomes apparent from the preceding discussion that a computer system designed to operate in conjunction with an existing network analyzer is probably the most practical means for solving routine transient-stability problems. It is felt that the computer units of such a system should fulfill requirements of space, reliability, simplicity, cost, precision, and accuracy, and that their application should not require appreciable modifications of present analyzer design. In other words, the computer system should be an accessory to the analyzer, and not vice versa.

A complete computer installation is visualized as consisting of a group of computer units, each unit controlling a phase shifter as a regulator during steady-state operation and as a computer during transient studies. A central multichannel recording device would record rotor-position data during transient-stability studies. The computer units should be sufficiently small so that they can be mounted directly on or adjacent to each phase shifter. The reliability and simplicity of the computer installation should be commensurate with that of the analyzer itself. A suitable criterion for the reliability of the computer in daily operation is that shutdowns of the order of 1 day shall occur less than 6 times a year. Moreover, the computer should be simple enough so that an operator can obtain satisfactory results following a short period of training.

The cost of the computer installation should bear a reasonable relationship to the cost of the network analyzer and to the savings which it is to effect. Based on an average percentage of the total analyzer operating time used for transient-stability studies, a reasonable figure for the cost of the complete installation might be about 20 per cent of the cost of a network analyzer. The value of the computer units as regulators for steady-state power-flow studies depends on the individual network analyzer. This feature is valuable for the MIT network analyzer because the high internal impedance of the phase shifters frequently makes their manual adjustment time consuming.

In the design of a computer system the most important performance specifications are precision and accuracy. When operating as a regulator, the computer unit should maintain the power output of its phase shifter to within 1 per cent and the voltage to within 1/2 per cent of the desired values, as measured by the master instruments at the metering desk. Such precision is normally obtained with manual adjustment of the phase shifters, where the instruments connected at the terminals of the phase shifters are calibrated from the instruments at the metering desk. The narrow tolerances are not predicated on the accuracy of corresponding power-system data on which studies are based, but on the desire to be able to reproduce part or complete sets of readings for identical terminal conditions on identical systems set up at different times. The same criterion can be applied to the results of transient-stability studies; a reproducibility of 1-to-2 per cent is desired even though the accuracy with which the solution describes the actual system phenomena is much poorer because of the simplifying assumptions made in setting up the problem.

The specification of accuracy affects the selection of two basic components of the computer unit: the power-sensing element and the integrators. The power-sensing element can take the form of an electronic wattmeter, which has not yet been devised to the required accuracy; it can be a dynamometer wattmeter, which has the required accuracy but whose indication must be read by photoelectric, capacitance-bridge, or other methods; or it can be a watt-hour meter which serves also as an integrator of the power reading. The choice of a power-sensing element with the required accuracy and reliability is one of the key problems in realizing an actual working unit. The factors governing the selection of a suitable integrator from the large class of devices for doing such work are discussed in the following.

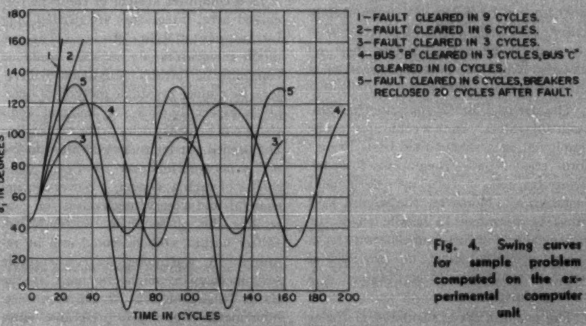

Fig. 4. Swing curves for sample problem computed on the experimental computer unit

Integrating Devices

Watt-hour meters are used as the actual computing elements of the experimental computer unit because these highly developed instruments are a simple and accurate means of integrating electric quantities. Since they cannot be loaded mechanically, a servomechanism must be used to position the output member of each integrator in accordance with the disk position. Any error-sensing device of this servomechanism which is mounted on the disk must be light in weight to keep down bearing friction and must function without imposing any other static friction torque on the meter shaft. Ordinarily, the static friction torque of the watt-hour meter bearings and register is compensated for by the light-load compensation of the meter. This compensation is unidirectional, hence, it cannot be used in computer service where the rotation of the meter disk can be both clockwise and counterclockwise. Of the available pickup devices capable of meeting these stringent loading requirements, an optical pickup was chosen for its comparative simplicity.

The choice of a watt-hour meter for performing the first integration in a computer unit is obvious since its output signal is directly proportional to the required time integral of the power difference $(P_{ik}-P_{ok})$. However, there are several devices other than a watt-hour meter which can be used to perform the second integration in the computer unit. Mechanical integrators come to mind immediately, but they are very expensive devices. The integrators of certain electronic analogue computers are another possibility, provided that their computing speed can be slowed down sufficiently for the purpose at hand. Since both mechanical and electronic integrators require follow-up servomechanisms of about the same complexity as those used with the watt-hour meter in the experimental computer, very little is gained by the use of these other integrators unless they are already available as components of a general-purpose computer.

The use of a digital computer has also been suggested. Such a computer can be employed on a shared-time basis to perform one or both integrations for each computer unit, in turn, in a permanent installation. However, the digital unit must be very fast to handle all of the phase shifters in turn and elaborate high-speed switching must be provided if accurate results are to be obtained in a reasonable time.

The use of a speed-regulated motor as an integrator was seriously considered. The output member of the first integrator would furnish the reference signal for a regulator which controls the speed of the motor used to position the phase shifter[11]; the position of the motor shaft is thus made proportional to the time integral of the output of integrator no 1. This system was not used because it was simpler to employ the watt-hour meter servomechanism design already developed for integrator no. 1.

Conclusions

The experimental computer unit described in this paper represents one of many approaches toward the development of a complete computer system for commercial service with a network analyzer. The performance of the unit is acceptable, but a considerable amount of engineering remains to be done to convert the experimental unit into a reliable and compact working model.

A complete computer installation would consist of a set of computer units, one for each phase shifter, with rotor-angle information fed from each computer unit to a central multichannel recorder. The computer units would also serve as power and voltage regulators for the phase shifters when the analyzer is used for steady-state power-flow studies. For transient-stability studies, the initial conditions would be established by the computer units acting as regulators. The units would then be converted to computer duty by setting in the machine-inertia constants and moving several levers. Starting the recorder and applying the fault to the system would start the computation. A time scale of 5-to-10 minutes of computer time for each second of system time would make recording and switching operations comparatively simple procedures.

In a computer system of the type discussed here, integrators are needed only for transient-stability studies. The use of the integrators of a separate analogue computer of suitable design may, therefore, be a more favorable method of operation, especially since the analogue computer can be utilized for other tasks when not needed for transient-stability studies on the network analyzer. For each phase shifter of such a system, a power-sensing element and a servomechanism for controlling the phase angle of the phase-shifter output voltage would still be required. A wattmeter with a suitable servomechanism might be used as the power-sensing element; however a watt-hour meter is obviously preferable, since it performs one of the required integrations as well as the power-sensing function. For steady-state power-flow studies the power-sensing element and the phase-shifter servomechanism can be combined to form a power regulator without the need for the integrators. Final evaluation of the usefulness and economic advantage of such a computer system in daily service can only be made after a network analyzer has been equipped with this system.

Appendix I. The Transient-Stability Problem

The rotors of the synchronous machines of a power system in steady state run at synchronous speed and, therefore, occupy fixed angular positions with respect to each other and to a synchronously rotating reference. A fault or other disturbance in the system results in a change in rotor speeds and angular positions. These changes are of interest, since synchronism will be lost if the angular displacement between rotors becomes too large.

The solution of a multimachine transient-stability problem thus requires the determination of the rotor angle of each synchronous machine in the system as a function of time following an initiating disturbance. This rotor angle is determined by the torque relationship governing the behavior of any rotating machine

$$\text{Inertia torque}+\text{damping torque}=\text{input torque}-\text{output torque} \quad (7)$$

Thus, for the kth machine in an n-machine system

$$J_k\frac{d^2\alpha_k}{dt^2}+\text{damping torque}=\text{input torque}-\text{output torque} \quad (8)$$

where

J_k = polar moment of inertia of the kth machine and its prime mover

α_k = rotor angle of the kth machine measured from an arbitrary fixed reference

Multiplying each term in this equation by the synchronous speed of the machine yields the following relationship[12]

$$M_k\frac{d^2\alpha_k}{dt^2}+P_{Dk}=P_{ik}-P_{ok} \quad (9)$$

where

M_k = inertia constant of the kth machine and prime mover

P_{Dk} = damping power of the kth machine and its prime mover

α_k = rotor angle of the kth machine measured from an arbitrary fixed reference

P_{ik} = mechanical power supplied to the kth machine by its prime mover

P_{ok} = synchronous power output of the kth machine measured at the air gap

Equation 9 is actually valid only if the speed of the machine is equal to its synchronous speed; however, use of this equation generally yields results of engineering accuracy in ordinary transient-stability problems where the speed does not depart materially from synchronous speed.

It is generally assumed that the damping power P_{Dk} can be neglected and that the angle

$$\alpha_k = \omega_{sk} t + \delta_k \tag{10}$$

where

ω_{sk} = synchronous speed of the machine
δ_k = phase angle of the voltage behind the transient reactance of the kth machine

With these assumptions, equation 9 can be written as

$$\frac{d^2\delta_k}{dt^2} = \frac{1}{M_k}(P_{ik} - P_{ek}) \tag{11}$$

Double integration of this equation yields equation 1.

Discussion

Allan N. Greenwood (University of Toronto, Toronto, Ont., Canada): The authors are to be complimented on having devised what would appear to be a robust and comparatively simple analogue for a synchronous machine. A principle feature of this device is the feedback loop which causes the phase shifter to be actuated in accordance with the differential power. This, or some similar feature, is apparent in all the analogues referred to in the paper, with the possible exception of Robert's Micromachines. Essentially the device has to be "told what to do," the intelligence is conveyed by the feedback circuit to be subsequently interpreted by the integrating elements.

I should like to draw attention to what I consider a simpler device, fundamentally simpler because there is no feedback circuit. The equipment responds of its own accord to a disturbance on the analyser, and as far as possible it is arranged that its response is the same as that of an alternator confronted with a similar stimulus in a system proper. The original idea was put forward in 1938 by W. S. Stuart of the University of Leeds; he and R. F. Linsell carried out some preliminary work at that time, and demonstrated the possibilities of the device. Much later Linsell published a short note on the work.[1] More recently the project has been pursued further at Leeds by C. B. Cooper.

The device resembles a selsyn, its stator accommodates a polyphase winding, which sets up a sinusoidally distributed rotating flux when supplied with balanced polyphase currents, its rotor carries a single-phase winding which has a sinusoidal electromotive force induced in it when cut by the rotating flux of the primary. The magnitude of this electromotive force can be regulated by the primary applied voltage, its phase relative to any fixed datum will depend upon the angular position of the rotor. The rotor is connected electrically to the analyser; arranged thus it functions as a generator unit. The rotor does not rotate but takes up an equilibrium no-load position, from which it can be disturbed only by applying a torque. A torque in one direction results in a transfer of energy to the analyser, the device "generates," a torque in the opposite sense causes the device to draw power from the analyser: it "motors." The shaft torque represents the input to the machine, it can be supplied by a weight on a string around a pulley on the shaft, or more elegantly, by electromagnetic means. The power-angle curve of the model can be made to resemble quite closely the corresponding characteristic of an alternator.

In an n-machine system $(n-1)$ such generators would be connected to the network at appropriate points, the nth source would be a bus bar which would also serve as a reference. Because the generator voltages and inputs can be readily adjusted, it should not be difficult to balance such a network for a load flow study.

To simulate transient conditions with such an arrangement it only remains to endow each unit with inertia corresponding to that of the parent machine it is intended to represent. In this regard there is a certain freedom of choice, the same freedom a that enjoyed by the authors in assigning values to their constants K_1K_2 and I. It is the ratio of torque to inertia which fixes the time scale for the swings of the models when the system is disturbed. The present aim is to have them swing at the same rate as the machines proper, but this may prove difficult to achieve.

Asynchronous damping forces should be simulated with ease on such a model, and it is not inconceivable that effects of governors might also be introduced. One of the chief difficulties do date has been that of reducing bearing friction in the analogue. It is hoped that a full report on the work will be published in due course.

1. Methods of Assessing the Stability of an A.C. Power System, R. F. Linsell. *The Engineer*, London, England, vol. 192, 1951, p. 332.

James E. Van Ness (Northwestern University, Evanston, Ill.): The paper presents an interesting device for improving the usefulness of a network analyzer. The use of this type of equipment, both in transient stability problems and steady-state problems, will greatly increase the value of any network analyzer.

The watt-hour meters provide a convenient means of combining the power-sensing element and the first integrator. However, they add to both the size and cost of the unit. I have found that an electronic device such as we have used for this purpose (see reference 9 of paper) is very reliable. No mention is made of a driving amplifier for the integrator. Is the burden low enough so that it can be connected directly to the network analyzer? The authors state that the reason for using a watt-hour meter for the second integrator instead of a speed-regulated motor was that it was simpler. Might it not be worth while in a final design to use as an integrator the elements of the servomechanism that are required anyway to drive the phase-shifter? This would reduce the unit's size and cost.

While I agree that it is advantageous to reduce the time scale, I do not think it necessary to go so far as is indicated in this paper. Our system reduces the time scale by a factor of 10. At this speed, a simple relay system can easily perform switching operations, and more conditions can be evaluated in a shorter time.

In using the system for steady-state operations, we intend to leave one of the integrators in the loop instead of removing both of them, as suggested by the authors. This will have the advantage of reducing the steady-state error of the system to zero as is commonly done in servomechanism. The constants of the system can be adjusted so that the time delay introduced will be negligible.

A. Kusko and P. N. Heller: The authors wish to thank Mr. Greenwood for calling attention to further work being done, and they feel that it would be of interest to learn the final results of this investigation.

The interest shown by Professor Van Ness is appreciated. Space in a network analyzer installation is not so limited as to prohibit the use of watt-hour meters as computer elements, especially since their remarkably low cost, inherent accuracy, freedom from drift and long life give them a decided advantage over electronic watt meters in multigenerator installations. The experimental computer unit was installed on the MIT network analyzer which operated with a base current of 1 ampere. It was therefore possible to connect the potential coil of watt-hour meter no. 1 directly across the phase shifter terminals. The current coil was connected between the potential coil and the network representation on the analizer. Watt-hour meter no. 1 would, of course, be left in the circuit when the unit is used as a power regulator so that there will be an integration in the regulator loop.

The use of a watt-hour meter for the second integration was prompted by the desire to save the engineering time necessary to develop an alternate means of integration of equal accuracy. The same considerations will influence the final design since development costs form a major portion of the price of a commercial installation.

It was felt that the slow computing speed would not be particularly objectionable since the preparations for a transient stability run would still require about as much time as the actual computation. A slow computing speed improves the accuracy of the computer units and makes it possible to avoid the inaccuracies and complications of high-speed recording.

A Circuit for Measuring the Resistance of Energized A-C Windings

R. E. SEELY
MEMBER AIEE

A SIMPLE means of measuring the electrical resistance of a-c energized windings has long been desired inasmuch as it would permit the determination of winding temperatures while the windings are operating under actual load conditions. The circuit as outlined in this paper makes such measurement possible.

Discussion

Present Methods

The present procedures for determining windings or coil temperatures are either thermometers or thermocouples or to calculate of the winding temperature from winding resistance values obtained at room temperature and after shutdown. Each of these procedures has certain inherent disadvantages.

The inherent disadvantages of thermometers for measuring winding temperatures are:

1. The thermometer tends to measure only the temperature of the spot where it is located and, in general, can only be used in an attempt to measure surface temperatures of winding.
2. There is frequently a considerable difference between the temperature as measured by a thermometer and the actual surface temperature of a winding. This difference between actual surface temperature and the thermometer reading can vary considerably, depending on the manner in which the thermometer is applied to the winding.
3. Because of the poor thermal contact between a thermometer and a winding, there can be a large temperature lag between them when the winding temperature is changing rapidly.
4. The thermometer frequently cannot be applied to the windings of a small apparatus without modifying the enclosure of the apparatus.

The disadvantages of a thermocouple for measuring winding temperatures are:

1. The thermocouple measures only spot temperatures.
2. There can be a wide variation in the thermocouple temperatures resulting from the manner in which thermocouples are applied to the windings.
3. The use of different types of thermocouples and of different size thermocouple wire can also result in a considerable difference in the measured temperature.
4. There can be temperature lag between the winding temperature and the thermocouple temperature when winding temperatures are changing rapidly.
5. It is frequently necessary to disassemble the apparatus under test to install thermocouples.
6. With hermetically sealed apparatus, it is necessary to build special test units to bring out the thermocouples.

The method of determining winding temperature by measuring winding resistance after shutdown also has the following inherent disadvantages:

1. Accurate winding resistance measurements cannot be made because of the changing resistance.
2. Since resistance readings cannot be made immediately after shut down, it is general practice to obtain a number of resistance readings after various time intervals and to plot these values back to zero time on logarithmic graph paper. This procedure is time-consuming and somewhat inaccurate since the cooling curve is not entirely logarithmic.
3. Winding temperatures cannot be followed under changing load conditions by this method.
4. Equipment such as refrigeration equipment cannot be frequently shut down during tests without disrupting the entire test.

New Resistance Method

It will be realized that, if attempts were made to measure the resistance of an a-c energized apparatus using a Wheatstone bridge or an ohmmeter, the alternating current voltage would damage or burn out the bridge or ohmmeter. Even if it were possible to connect the bridge directly to an a-c energized apparatus it still would be impossible to measure the resistance of this apparatus since its resistance would be paralleled by the resistances of all of the other loads on the line and, also, by the resistance of the secondary winding of the line transformer. It was, therefore, necessary to devise a circuit which would circumvent these two basic obstacles.

The circuit in Fig. 1 illustrates the manner in which this was accomplished. First, the voltage problem was surmounted by the use of a substantially equal and opposite bucking voltage as

Pt
19

supplied by a potential transformer. This allows a bridge or ohmmeter to be connected to one terminal of the apparatus on test and to one side of the secondary of the transformer since there is substantially zero voltage between these points. It was originally thought necessary to use a variable transformer to buck the voltage to zero, but it was found unnecessary since a few volts of alternating current would not adversely affect a bridge.

The necessary isolation of the windings under test so that the direct current from the bridge or ohmmeter will not flow through the other paralleling resistance in the circuit is accomplished by the use of the capacitor bank in the circuit of Fig. 1. It will be noted that the primary winding of the bucking transformer is also on the line side of the capacitor bank. As such, this permits the bridge to measure the sum of the resistances of the winding in question, the secondary of the transformer, and the leads. The actual winding resistance is then obtained by subtracting the resistances of the transformer and leads from the total resistance as obtained from the bridge. The winding temperature, of course, can then be obtained by using the equation

$$T_h = (R_h/R_c)(K+T_c) - K$$

where

R_h = hot winding resistance
R_c = cold winding resistance at the start of test
T_c = cold winding temperature as obtained from thermometer at start of test
K = constant

For temperatures in degrees centigrades, this constant is 234.5 for copper windings and 221 for aluminum windings. For temperatures in degrees Fahrenheit, it is equal to 390.1 for copper and to 365.8 for aluminum. Fig. 2 illustrates how this circuit can be used in reverse to measure the resistance of a-c energized windings which supply a-c power such as alternator windings or a transformer secondary winding.

Whereas, the circuit shown in Figs 1 and 2 illustrates the fundamentals of this circuits operation, it will be realized that further circuit refinements were necessary for successful use in a test department. The circuit shown in Fig. 3 incorporates refinements such that it can be successfully used to measure the winding resistance of either single-phase or polyphase equipment. To measure the resistance of energized polyphase equipment, it is necessary to insert another capacitor bank in the third line so that the direct current of the bridge cannot flow back through the line transformer. With grounded neutral polyphase equipment, it is necessary to go a step further and to have a capacitor bank in all three supply lines to isolate the flow of bridge current. When used with wye-connected polyphase equipment, the resistance of 2-phase windings in series is measured. With delta-connected equipment, the resistance of a phase winding paralleled by the other 2-phase winding in series is measured.

It will be noted that a 4-pole double-throw switch has been incorporated into the circuit, as shown in Fig. 3. This switch has a number of purposes. First, it serves to connect the potential transformer into the circuit when the switch is thrown to its READ or ON position. This is desirable so that the potential transformer is only energized when it is necessary to take a resistance reading. In this manner, there is very little heating of the transformer which would change the resistance of the transformer secondary winding. It should again be noted that the purpose of the potential transformer is only to supply a bucking voltage and not to supply power. As such, the temperature rise would normally be small even if it were energized continuously. In the OFF or CHECK position, as shown this switch shunts the capacitor banks *C1* and *C3* and connects the secondary of the potential transformer directly to the bridge terminals. Normally, the impedances of the capacitor banks are such that there is a few volt drop across them at the full-load capacity of these circuits. It is desirable to shunt the capacitor banks *C1* and *C3* such that there will be no voltage drop across them when the circuit is OFF. This allows voltmeters and wattmeters to be connected on the line side of the circuit such that their readings will be correct when the circuit is in the OFF or CHECK position. These meters can be connected to the load if provisions are made to disconnect them while a resistance reading is being made. Connecting the secondary of the transformer to the bridge terminals on the CHECK or OFF position permits its secondary resistance to be checked periodically for any slight change of the tare resistance. It will be noted that two blades of the switch to the secondary of the transformer are connected in parallel. This was found to be desirable to obtain a low and stable resistance through the switch.

The circuit, as shown in Fig. 3, is intended to be used to make periodic resistance readings during a heat run, but it also can be used to make continuous readings should they be desired. To do this, it is necessary that a circuit be energized for a few hours at the desired test voltage with the switch in the READ position and with no load being applied to the load terminals. This permits the potential transformer to heat and allows its tare resistance to become stabilized, as can be determined by occasionally switching to the CHECK position.

Another refinement of the circuit in Fig. 3 is the addition of a capacitor bank *C2* directly across the bridge terminals of the circuit. The use of this additional capacitor bank was found to be desirable to minimize the effect of line surges on the galvanometer of the bridge. Without this additional capacitor bank, it occasionally was found that the switching surges on the line or a pulsating motor load would cause the galvanometer to be unstable. To minimize galvanometer unstability caused by

Fig. 5 (right). The latest circuit enclosure for measuring resistance of a-c energized windings. This circuit is rated at 20 amperes, 250 volts, 60 cycles, single- or polyphase, and 0.2 to 100 ohms

Vol. Pt. 1 1955

these surges, it has also been found desirable to operate this circuit from a "stiff" line or, better yet, to operate from a separate voltage regulating transformer or separate alternator, if available. The addition of a pilot light to the circuit is desirable so that the circuit will not be energized any longer than necessary. In this manner, heating of the transformer is very slight and, hence, the change in the transformer resistance is negligible.

In the original circuits which were built about 7 years ago, standard 1- and $1^1/_2$-kva power transformers were used because they were readily available. They were connected for 230/230-volt operation, and as such the circuits could be used for voltages up to about 250 volts. Transformers of this size were employed so that the tare resistance of their secondary winding (about 0.3 ohm) would not be greater than the resistance of the induction motor windings to be measured. It was found desirable to limit the use of these test circuits to an apparatus having a resistance greater than the tare resistance to obtain sufficiently accurate resistance reading. It was soon realized that, if a special potential transformer having a much heavier secondary winding than the primary winding were used, considerable saving in weight could be realized. Consequently, special potential transformers were designed and have been used in circuits built during the last few years.

The original circuit also used banks of standard 110-volt a-c electrolytic motor-starting capacitors, rated 850 to 900 microfarads, since they were readily available. Here again, it was realized that these capacitors were many times larger than needed, since even under full loads the voltage across them was only 4 or 5 volts. Subsequently, electrolytic capacitors rated 15 volts a-c and having a capacity of 4,000 to 9,000 microfarads were obtained. As such, it has been possible to reduce the size of the capacitor banks by a ratio of about 10 to 1. At this point it should be mentioned that the internal leakage resistance of these capacitors, in effect, parallels the resistance being measured, and establishes the maximum resistance which can be measured with sufficient accuracy. It is for this reason that a maximum resistance rating is applied to a given circuit.

Fig. 4 shows one of the original circuits being used to determine the temperature of a motor winding and the various circuit components. Fig. 5 shows the latest type of measuring circuit box which uses the circuit shown in Fig. 3 and the special transformer and capacitors described in the foregoing. This circuit box has been rated at 20 amperes, 250 volts, 60 cycles and 0.2 to 100 ohms resistance. It weighs 116 pounds, most of it being the transformer. Although this circuit box has been rated at 60 cycles, it has been used at frequencies from 25 to 430 cycles. When used at other frequencies, the volt-

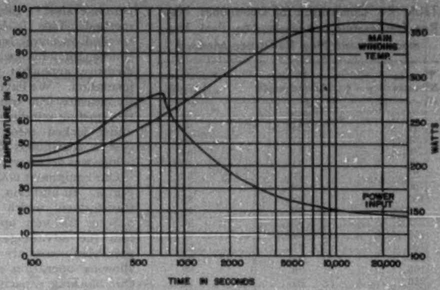
Fig. 8 (right). Curves of winding temperature and power input of a 1/6-horsepower hermetic refrigerator motor



age and current rating of the circuit is varied by the ratio of the odd frequency to the rated 60-cycle frequency.

Although, the measuring circuit was originally developed to determine the temperature of motor windings by the resistance method, it also has been used to determine the winding temperature of alternators and transformer windings. Fig. 6 shows the heating and cooling curves of the primary and secondary windings of a 1-kva transformer, as obtained by using measuring circuits in both the primary and secondary windings. In this test, the transformer was first loaded to full and then reduced to 50-per-cent load after $5^{1}/_{2}$ hours. Fig. 7 shows a temperature rise curve of the winding of a 1.5-kva 3-phase 115-volt 430-cycle motor alternator which was first loaded to a full load and then to 50 per cent load.

Fig. 8 illustrates a very important use for this measuring circuit. Shown here are curves of winding temperature and power of a 1/6-horsepower hermetic refrigerator motor, as obtained when the refrigeration system reduced the refrigerator cabinet from room temperature of approximately 40 degrees centigrade to its normal operating temperatures. It will be noted that, under such a test, the power and winding temperature reach a peak and then fall off as the cabinet temperature is pulled down. Without the use of this resistance-measuring circuit it would be difficult or impossible to determine accurately the peak winding temperatures.

Conclusions

Since its conception, this circuit for measuring energized a-c winding resistance, as discussed in the foregoing, has proved to be a highly desirable piece of test equipment, and its use is continuing to expand. Because of this circuit, the method of determining the temperature rise by the resistance change method is becoming more widely accepted.

◆

Discussion

R. F. Fricke (Westinghouse Electric Corporation, Lima, Ohio): The measurement of motor temperatures under load has always been a difficult problem. Several methods of measurement are currently in use, and each method has its particular advantages and disadvantages. The thermometer method defined and used by AIEE and the National Electrical Manufacturers Association is simple and direct. However, winding temperatures measured by thermometer are necessarily low since the bulb cannot be placed in small, high-temperature cavities. Thermocouples usually permit us to associating the measuring device more closely with the source of heat. As a result, this method is quick-acting, and temperatures measured by thermocouple more nearly approach the actual temperature of the element measured. However, test results with thermocouples depend upon several variables, one of which is the ability to make good connections with the surface of the element to be measured. Furthermore, unless thermocouples are wound into the machine, only end-turn temperatures can be measured and the possible high-slot temperatures remain unknown. Temperature indicated by resistance readings taken after shutdown, then extrapolated to shutdown time, gives a more accurate evaluation of over-all average winding temperature. The greatest drawback to this method is, of course, the fact that only final temperature can be determined.

The resistance method of temperature measurement as described by the author solves many of these problems and adds only few. This method enables us to measure winding resistance while a motor is running and, by comparing with the cold resistance, calculate the total winding temperature. It should be noted, furthermore, that in all single-phase motors only the main winding temperature is measured. The Wheatstone bridge current is conveniently blocked from the motor auxiliary winding by an open starting switch or by the motor-running capacitor. Thus we gain the advantage of measuring the temperature only of the hot main winding—rather than some average of both phase windings.

The resistance method of temperature measurement presented in this paper is free of some of the difficulties encountered with thermocouples. It measures over-all average winding temperature and is not dependent upon location or the connection of a temperature-measuring element. This is of particular importance for correlation purposes when temperatures are measured repetitively, for instance, by a manufacturer, his customer, and the Underwriters' Laboratories. Inherent accuracy is as good as in other methods. Perhaps the most important disadvantage of the resistance method is its inability to measure hot-spot temperature.

When we investigated the use of this novel circuit several years ago, we felt it necessary to compare this method with the thermocouple method which then was, and probably still is, the most popular method of measuring fractional horsepower motor temperatures. We conducted heating tests on several motors while simultaneously measuring temperature by both methods. Stabilized winding temperatures from some of these tests are shown in Table I. It can be seen that temperature measured by resistance compares very favorably with that measured by the hottest thermocouple. This is fortunate, of course, because peak

thermocouple or hot-spot temperature, rather than average thermocouple temperature, is the limiting factor in motor design. We obtained the greatest difference between the two methods in open motors where the variation in air movement over the windings moved the hot spot, or caused it to vary farther from the average winding temperature.

Table II is a continuous record of a heat run, and shows that the initial rate of temperature rise is greater by the resistance method. This is logical, for the latter method measures temperature at the heat source (the wire itself) while thermocouples measure somewhat remotely on the wire insulation. We have also used this method to measure fast transient temperatures of the starting windings in split-phase motors under locked rotor conditions. For this case a continuous dial type of resistance bridge was necessary.

Our equipment is similar to that shown in Fig. 3. In addition, we use doubly wound transformers which can be switched for 115- or 230-volt operation, and thus obtain the advantage of a low resistance paralleled secondary on low voltage, while allowing operation at the higher voltage. Our blocking capacitor is made up of two 10,000-microfarad elements, one of which can be externally disconnected from the circuit.

Both capacitors are used on large low-resistance motors to reduce the unbalancing voltage drop across the capacitors. One capacitor is used on small high-resistance motors to increase the total leakage resistance of the elements. In this way the range of resistance which we are able to measure with the circuit is effectively doubled.

The author is to be commended on his interesting paper. I hope that it will serve to publicize this method so that it soon may be adopted as a standard in the motor industry.

R. E. Seely: I wish to thank Mr. Fricke for his very interesting discussion of this paper. I was particularly interested in the data comparing motor winding temperatures as obtained by peak thermocouple and by the resistance change method using the measuring circuit. The results obtained agree quite favorably with our results, as should be expected. Mr. Fricke advised that he has used the circuit to measure the resistance of start winding temperatures when a motor is stalled. We have also made a similar investigation, but wish to point out that erroneous results can be obtained if the winding resistance changes too rapidly. This error is apparently caused by the charging of the capacitor bank.

Mr. Fricke advises that in the circuits he has built, doubly wound transformers were used which can be switched for 115- or 230-volt operation. He also uses a switch for varying the amount of blocking capacitance. We have considered such additional refinements in the circuits which we built, but have not employed either because we felt that it would be desirable to keep the circuit simple to operate. Instead of varying the voltage rating of a circuit by switching, we have built individual circuits rated at 120, 240 and 480 volts.

The Propagation Mechanism of Impulse Creepage Discharges Over Oil-Immersed Surfaces

J. G. ANDERSON
MEMBER AIEE

T. W. LIAO
MEMBER AIEE

Synopsis: A fundamental study of the mechanism of propagation of impulse creepage streamers over an insulating surface is reported. The studies were made using high-speed cameras, still cameras, and special probes, to give a new picture of the creepage process. High-speed photographs show that impulse creepage in the nonuniform field is a stepped discharge process, remarkably similar to natural lightning except on a greatly reduced scale. Probe measurements display the variation of channel voltages with time and distance. The mechanism is discussed in considerable detail for both positive and negative polarities.

THE designer of electric apparatus is confronted with two types of electrical failure of solid insulation; puncture and creepage. Electrical failure by puncture has been studied extensively for many years, and its mechanism is becoming increasingly clear, at least in the case of pure solids.[1] However, knowledge of the mechanism of creepage failure is not nearly as complete. Considerable work has been done on surface discharges in gases[1,2] but a dearth of fundamental work exists on liquids. The latter is particularly true for impulse creepage over oil-immersed surfaces, a case of prime importance in oil-filled apparatus such as transformers and circuit breakers.

The few workers in this field have generally used a Lichtenberg figure or photo paper technique wherein the surface discharges move across or very close to a photo-sensitive surface.[3-5] This method has yielded some interesting results, but suffers from the fact that it does not give a record of the discharge with time. In addition, the propagation of discharges across a photo-sensitive surface may be different from the propagation across surfaces of practical insulation.

To study the propagation of these discharges over insulating surfaces, an investigation was undertaken with the use of high-speed and still cameras to record the streamer progression, and using a special probe technique to measure the rise and fall of potential in the creepage channel as it progressed. The results have given a new and clearer idea of impulse creepage in oil and hold promise of revealing new facts about the breakdown of liquids in general.

In studying the fundamental process of impulse creepage, a nonuniform field electrode configuration was used. Such a field was chosen for several reasons:

1. Experience has shown that in such a field, the velocity of the creepage streamers is slow enough to permit detailed measurements with available equipment.

Paper 55-36, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing November 16, 1954.

J. G. Anderson and T. W. Liao are with the General Electric Company, Pittsfield, Mass.

2. The discharge in a nonuniform field oil gap has been shown in a previous paper[4] to consist of stepped streamers similar to natural lightning. For comparison purposes it was found desirable to use a nonuniform field for this investigation also.

3. Nonuniform field creepage is a common phenomenon in the breakdown of oil-immersed insulating structures.

Instrumentation

A sketch of the basic technique used in these studies is shown in Fig. 1 and a photograph of the instrumentation in Fig. 2. A sheet of Kraft board insulation 14 by 14 by 1/8 inches was mounted vertically in a large lucite tank filled with commercial quality *10-C* oil. On one side of the insulation a flat-ended steel rod electrode 1/10 inch in diameter was pressed against the surface. This rod was connected to an impulse generator, and produced impulse streamers which moved out over the insulation surface. The other side of the insulation was covered with a grounded film of copper 4 mils thick, deposited directly on the material. On this copper surface three 0.2-inch square areas, $1^1/_2$ inches apart, were isolated from the rest of the grounded film by a 1/32-inch insulated boundary. The copper surface was directly connected to ground, but the isolated areas or probes were connected to ground through capacitors across which the plates of the cathode ray tubes were connected. Fig. 1 shows that the equivalent capacitance C_1 from the insulation surface to the probe and the capacitance C_2 from probe to ground formed a simple capacitance divider. C_2 was made about 1,000 times C_1, so that for every kilovolt of streamer potential on the barrier surface, 1 volt appeared across C_2. This voltage across C_2 was fed to the vertical deflecting plates of the cathode-ray tubes for display. The sweeps of the cathode-ray tubes were initiated by the impulse wave applied to the rod electrode. Thus a record of the approximate streamer potentials with time could be obtained. The low probe potential had negligible effect on the impulse creepage process.

Figs. 1 and 2 also show a high-speed Boys camera and a still (Leica) camera which were mounted outside the transparent lucite tank to photograph the discharges as they moved over the insulation surface. The high-speed Boys camera has been described in previous papers,[6,7] and was used to obtain a con-

tinuous time sequence of the progression of the impulse creepage discharge. In principle it consisted of a circular strip of film moving at high speed past a shutterless *f 2.3* lens. The film speed of 1.6 to 2.0 mils per microsecond allowed resolution of events 1 microsecond apart in time. A shutter was not necessary since all tests were made in darkness, and the discharge itself supplied the light recorded on the film.

The Leica camera was mounted at right angles to the Boys camera, and the discharge light fed into both cameras by use of a half-silvered mirror. This, of course, reduced the light to the Boys camera, and therefore in many cases the mirror was removed.

Fig. 1 also indicates that a 5/16-inch wide slit in line with the capacitance probes was arranged between the insulation and the camera to mask out the light from all discharges other than those passing over or near the probes. This greatly simplified the interpretation of the mechanism of progression, but necessitated photographing a large number of discharges before one would pass under the slit for any considerable distance.

During all tests, an impulse wave with a 1.5-microsecond front and at least a 7,000-microsecond tail was used. The reasons for using such a long-tailed wave were threefold:

1. It approximated a step-function wave, making a theoretical analysis of the impulse creepage propagation mechanism much easier because variations in applied voltage during the propagation of the discharges did not have to be considered.
2. With a long-tailed wave, long creepage discharges could be obtained over the insulation surface at a low voltage, permitting much thinner insulation sheets to be used without puncture.
3. The use of thinner insulation sheets permitted smaller probes and better probe resolution, so that the probe became sensitive only to discharges in its immediate vicinity.

With such a long-tailed wave it was found possible to obtain creepage discharges as long as five inches with only 120-kv impulse voltage.

The immersant used in these tests was good quality commercial *10-C* oil continuously circulated and filtered through a felt filter. The oil was not deaerated, since this would have greatly complicated the tests, but the insulation sheets themselves (after the probes were constructed) were treated with deaerated oil under vacuum and transferred to the testing tank under oil when the tests were started. During these experiments, the insulation surface was wiped free of residual charge with a grounded copper wire before the initiation of each creepage streamer discharge to prevent any accumulative charge effects from influencing the results.

Probe Calibration

To estimate the creepage streamer potentials, the capacitance divider C_1-C_2 was calibrated by placing a flat electrode on the insulation surface opposite the probe. A known voltage was applied to this electrode and the resulting oscillograph deflection measured. Deflection sensitivities of about 0.005 inch per kilovolt were obtained. Of course such a calibration was more accurate for large streamers having diameters approaching the 220-mil probe width. For streamers of smaller diameter an error was introduced because of the smaller streamer capacitance C_1, becoming about 50 per cent for a 50-mil diameter streamer. Thus the streamer potentials were always at least as high as those indicated by the probes and in many cases considerably higher. However, by observing the streamer channel diameter photographically, and allowing for effects of adjacent channels, branching, and other factors which tended to increase C_1 to a higher value, a better estimate of streamer potentials was possible.

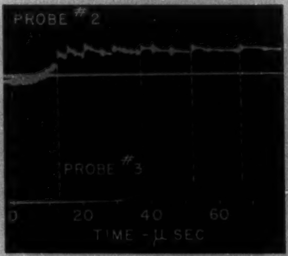

Fig. 6. Oscillograms of 120-kv negative-polarity creepage channel potentials. Crest voltage at probe 2 = 120 kv; crest voltage at probe 3 = 85 kv attributable to streamer not passing directly over probe

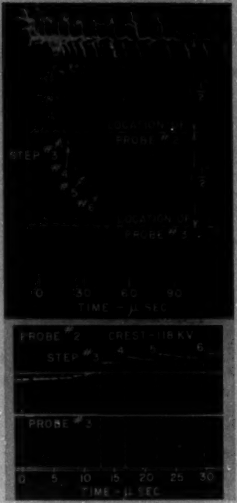

Fig. 7. Boys camera photograph and probe oscillograms of 120-kv negative-polarity creepage streamer

The probe resolution with regard to streamer location was determined by a wire 50 mils in diameter placed at various positions over the probe to simulate an impulse streamer. This simulated streamer was impulsed with 1 x 180-microsecond repetitive impulses of 1,000-volt amplitudes. The resulting probe voltages were measured by means of an amplifier and oscillograph at various wire positions parallel to the slit. Fig. 3 shows the resulting voltages measured. It may be seen that the probe sensitivity

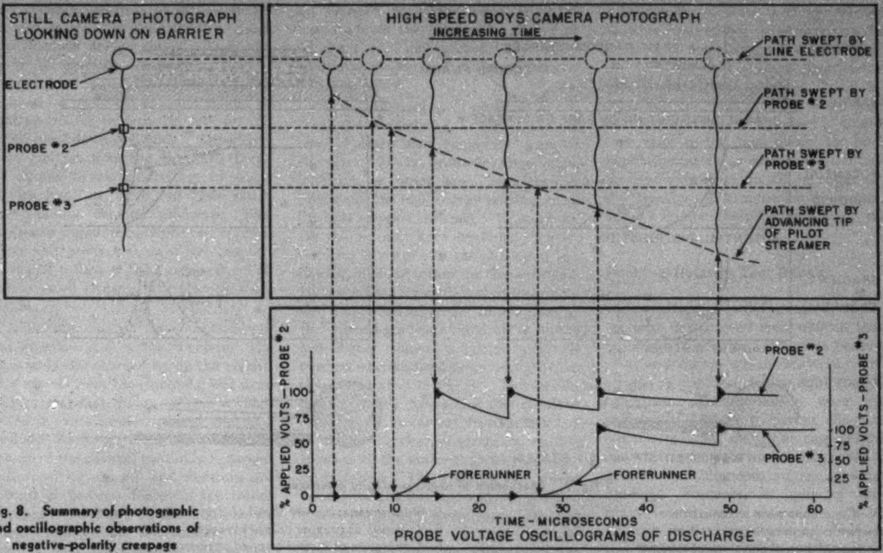

Fig. 8. Summary of photographic and oscillographic observations of negative-polarity creepage

drops rapidly as the wire is displaced from the center position, becoming 65 per cent at the probe edges and 25 per cent at a distance of one probe width away from center.

Negative-Polarity Test Results

When a negative-polarity impulse wave was applied to the rod electrode, impulse creepage streamers moved outward over the insulation surface in all directions from the electrode end. A typical still photograph of these streamers, taken without the mask and slit, is shown in Fig. 4. Here one can observe both the shrinkage of the creepage streamer channels as they moved out over the insulation surface, and the extensive branching that occurred.

When a single discharge was photographed through a slit by the Boys camera, its propagation over the insulation surface could be resolved with time. A typical result is shown in Fig. 5. Here, increasing time is to the right and the lengths and times of occurrence of the streamers are as shown. This photograph reveals that a single discharge (as seen by the eye or by a still camera) is actually composed of many bright streamers, called stepped streamers, all moving down the same channel with ever-increasing length. Each streamer exists for only 1 microsecond or less, and the interval between streamers generally increases with time from 1 microsecond or less at the beginning to 10 microseconds or more toward the end of the process. Furthermore, when one streamer branches, subsequent streamers usually branch at the same point, and most of the streamers appear to have bright spots at their tips. This type of propagation is commonly referred to as the "stepped" discharge, and has been found extensively in natural lightning,[7,8] in point-to-plane gaps in air[9] and recently in oil.[6,10]

A typical set of negative polarity discharge oscillograms is shown in Fig. 6. Probe 2 measured the channel potential at a distance of 1.5 inches from the origin at the rod electrode, and probe 3 measured the potential at a distance of 3.0 inches from the same point. On these oscillograms a small displacement of the zero line can be observed. This displacement is attributable to a small residual charge collection on capacitor C_2 during the tests, but it in no way modifies the probe frequency response to the potential variations of interest. It merely shifts the d-c response, and points out the desirability of having resistance compensation across C_2 in future tests.

In Fig. 7, a set of simultaneous high speed Boys camera photographs and oscillograms are shown. Comparison of the times of occurrence of the stepped streamers and sudden voltage increases on the oscillograms leads to the conclusion that the two are simultaneous, i.e., at the same time that the channel becomes a good conductor it emits light, resulting in a stepped streamer on the photograph. In this particular set of oscillograms, the voltage variations at probe 2 are shown in considerable detail. However, by the end of the sweep, the discharge is just beginning to arrive at probe 3, hence the latter shows no appreciable voltage variations in this short time.

Postulated Mechanism of Negative Impulse Creepage

Fig. 8 summarizes the results of photographic and oscillographic observations of a single streamer. A single creepage discharge at the top left of the sketch is one which might be observed by eye or by still camera. This discharge is shown by the Boys camera image at the top right to be a series of stepped streamers of ever-increasing length passing down the channel. Their velocity is extremely high and cannot be resolved by the camera. However, the over-all propagation velocity is much slower, because of the intervals of several microseconds between streamers, and 0.1 inch per microsecond is an average value.

Vol.
Pt. 1
1955

The probe oscillograms in Fig. 8 reveal several new facts about the creepage mechanism. For negative polarity the potential above the probe is essentially zero until the creepage process begins to arrive at that point. Then, in spite of the fact that the Boys camera has shown that the streamers propagate in a series of discrete steps, the potential above the probe first starts increasing in a gradual and practically uniform manner. This observation becomes of great importance when it is recalled that the stepped leaders of lightning are believed to be preceded by a faintly luminous, continuous discharge[8] (called the pilot streamer). It has been found difficult to explain the stepping process in lightning without the pilot streamer although this has never been photographed. The Boys camera shows that in oil, the same type of stepping discharge occurs, and the probe potential measurements indicate a continuous charge propagation ahead of the steps. Thus it appears to be a possible confirmation of the pilot streamer theory of the stepped discharge and further clarifies the creepage mechanism. Therefore the propagation of the apparent pilot streamer is sketched in Fig. 8 in dashed lines, since it is not luminous enough to be recorded by the Boys camera.

After the gradual build-up of pilot streamer potential, the channel potential suddenly jumps to practically full-line voltage, indicating that the channel has suddenly turned into a good conductor. The channel emits light momentarily at this instant, forming a stepped streamer and this light is recorded by the Boys camera. However, the light emission stops almost immediately, and the channel voltage over the probe begins a slow decay. (By this time the tip of the advancing pilot streamer has moved considerably beyond the point of probe measurement.) The channel potential decays for several microseconds, then the channel suddenly restrikes, a new stepped leader of longer length is formed, the channel potential again increases to approximately the applied voltage, and the process repeats. In general, the interval between steps seems to increase markedly as time increases, although the over-all propagation velocity appears to vary only from 0.1 inch per microsecond to 0.05 inch per microsecond.

Eventually, the pilot streamer-stepped streamer mechanism arrives at the next probe, and the same type of voltage variation is again recorded. Here, however, the rise of pilot streamer voltage appears more gradual and persists for a longer time, corresponding to the longer interval between stepped streamers. Finally, a stage will be reached where no more stepped streamers occur. The channel charge then slowly leaks to ground, in a period of several minutes, through the normal insulation leakage paths.

Based on the foregoing data, a step-by-step description of the discharge propagation can now be postulated. This decription is shown in Fig. 9, where, at *A*, the potential distribution and gradients along the insulating surface are sketched before any ionization or corona occurs. The gradient is highest at the electrode edge, and rapidly decreases with distance along the surface. (It should be noted that this entire process is taking place at initial gradients about three times the critical corona starting gradient.)

At *B*, a stray electron in the high gradient region has struck a neutral oil molecule knocking off an additional electron. Each of these electrons strike other molecules, knocking off still more electrons. The electrons, being more mobile, are forced away from the electrode toward the tip of the streamer by the high field, leaving the immobile positive ions behind.

The electrons near the tip produce a sufficient field to enable the pilot streamer to continue its progression. The positive ions enhance the field at the electrode. As the pilot progresses further, more positive ions are produced. Thus the electrode gradient is continuingly increased until it becomes so high that it results in a high field emission similar to that postulated by Von Hippel[11] for the initial breakdown of liquids. These electrons emitted from the electrode charge the channel to near line voltage, causing a sudden jump in probe potentials and a reduction of channel gradients. This facilitates rapid recombination of electrons and positive ions in the channel, giving off a flash of light and heat. The first stepped streamer therefore is completed.

After the charges have recombined, the situation at D of Fig. 9 exists. The channel is still charged up by the surplus of electrons from the electrode, but is no longer emitting light. Now, a high gradient exists at its tip, and the pilot streamer continues from this point. As the tip of the channel continues to propagate, positive charges and electrons are formed as before. Electrons are forced outward toward the tip and the heavier positive charges are left behind. However, a new complication now arises. The channel gradients near the tip begin to pull electrons from the old stepped streamer channel. As these electrons move forward to fill the advancing tip of the pilot streamer, the electron density in the old channel starts dropping. This results in the gradual fall in channel potential shown in the oscillograms after a stepped streamer has occurred. Accordingly, gradients must now be increasing along the channel as shown at D in Fig. 9.

At this point, it is interesting to note that the charge concentration at the tip of the streamer has been postulated as primarily electronic. One may also conclude that, after Meek,[2] the streamer tip will continue to progress as long as the tip gradient exceeds the minimum breakdown strength of the dielectric. For a very small-area electrode such as the streamer tip might represent, the negative polarity impulse breakdown strength of oil might approximate 1,500 volts per mil. Electron mobilities in oil are not well known but a value of 1 centimeter per second per volt per centimeter might be representative, when one extrapolates from the known electron mobilities in other liquids. When the probable tip gradient is multiplied by this extrapolated mobility (see equation 5), a tip velocity is arrived at of about 0.59 centimeter per microsecond, or 0.23 inch per microsecond. This calculated value of tip velocity is of the same order of magnitude as the measured velocity of 0.1 inch per microsecond, and gives additional assurance that the mechanism is as described.

During the build-up of gradients in the channel described at D in Fig. 9, the old channel must have somewhat changed character. It is probable that some hydrogen or other gases have formed because of the high energy released from the first stepped streamer. In addition, the channel may have expanded slightly, resulting in more of a gas phase and less of a liquid phase within the channel itself. Its breakdown strength is therefore probably somewhat lowered. In any case, as the channel gradients build up to higher and higher values, a critical point is reached wherein breakdown occurs in the channel as at E in Fig. 9. This breakdown probably occurs near the tip of the old stepped streamer channel and, by distorting the channel gradients, rapidly grows until the entire channel turns into an avalanche. Electrons are then swept toward the channel tip, and the positive charge left behind again causes electron emission from the electrode surface. This electron emission charges up the channel to line potential for a second time as at F in Fig. 9. The channel gradients fall to zero, positive and negative charges recombine, and light is emitted, forming the second stepped streamer.

This alternate propagation of pilot streamer and stepped streamer must then continue as before, but cannot continue indefinitely. Some electrons attach to impurities in the oil or on the insulating surface, becoming negative ions which are relatively immobile and cannot feed the advancing tip. Others are shunted to other channels by branching. Still others lose their energies by molecular excitation and other processes. The net result is that the supply of electrons to the tip of the pilot streamer diminishes as the streamer advances. This diminution in electron charge at the streamer tip must cause the tip to shrink in diameter, if the tip gradient is to remain sufficient to keep the oil breaking down. As the streamer shrinks in diameter, it takes a longer time to pump an equal amount of total charge from the old stepped streamer channel into the shrunken pilot streamer ahead of it, and consequently a longer time for the channel gradients to build up to a value sufficient to cause a new stepped streamer to form. This theory of the process is advanced as an explanation of the increase in interval between stepped streamers as the number of steps increases.

Eventually a state will be reached wherein the falling gradients in the streamer do not feed enough electrons into the tip to maintain a critical tip gradient. The streamer channel then gradually decays, and the limit of impulse creepage has been reached. Of course, if at any time prior to this final decay, the pilot approaches near a grounded metal surface the gradients at its tip will be enhanced, the streamer will turn toward the surface, and a complete creepage breakdown will ensue.

Positive-Polarity Test Results

Acquisition of valid positive-polarity creepage data proved more difficult than for negative polarity. This was because positive-polarity streamers were more erratic in direction, length, and channel brightness. The streamers were not sufficiently straight to permit adequate slit photography, and in no case did the same streamer pass over both probes to give two simultaneous streamer voltage readings. However, in spite of this, many records were obtained which indicated that positive-polarity creepage has considerably different characteristics from those of negative-polarity creepage.

A typical set of positive-polarity channel oscillograms is shown in Fig. 10. The upper oscillogram is from probe 2 and the lower from probe 3. In this case, probes 2 and 3 were not measuring the same streamer as that already discussed. However, by comparison with Fig. 6 it can be seen that positive-polarity creepage streamer potentials build up in a different manner than those of negative polarity. The sudden jumps in potential are still present, but the increase is essen-

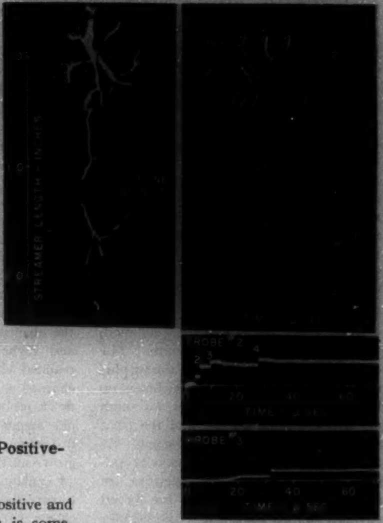

Fig. 12 (right). Still and Boys camera photographs and probe oscillograms of 120-kv positive-polarity creepage streamer

tially steplike, and the gradually increasing forerunner voltage (pilot streamer) is missing. Also the decay of potential after each increase is generally smaller than that for negative polarity.

In Fig. 11 are shown a still photograph and a high-speed photograph of a positive-polarity discharge passing down the slit. In the still photograph on the left, the edges of the slit appear in dotted lines and several streamers can be seen behind the slit. These streamers are shown by the high-speed photograph on the right to consist of many discharges, separated in time, but frequently passing down the same channel. Their velocities are erratic, some streamers, such as streamer *A* reaching distances of 1.5 inches or more in a few microseconds, whereas streamer *B* requires almost 50 microseconds to reach a distance of 4 inches. In general, the average propagation is faster in the region near the electrode. However, judging from many photographs and oscillograms, an average velocity of 0.1 inch per microsecond is estimated. Branching is also erratic, that at point *C* being a typical example. Occasionally, discharges have been observed to ignore a section of a previously formed channel and strike out in a new direction. This type of behavior appears to be because a breakdown takes place from the surrounding oil to the channel rather than from the channel tip outward.

Fig. 12 shows a simultaneous set of still and high-speed photographs and streamer channel voltage oscillograms. Here again, probes 2 and 3 may not be measuring potential variations in the same streamer channel and hence cannot be compared with confidence.

Postulated Mechanism of Positive-Polarity Creepage

The general picture of the positive and negative streamer mechanism is somewhat the same. However, there are several distinct differences because of opposite electronic movements for the two polarities. First, the channel of a positive stepped streamer does not jump up near line potential on the first discharge but builds up in steps after each stepped streamer. This is apparent because the measured channel potential is proportional to the net positive charge (above the probe), which does not come from the electrode emission as for the negative polarity but depends on the degree of ionization; consequently more charges are available after successive ionizations. Also, there is no pilot streamer ahead of the stepped streamers. Finally, the channels are more crooked and the branchings more random than those of negative polarity. This can be explained by a step-by-step description of the streamer propagation as shown in Fig. 13.

At *A* in Fig. 13, an electron is shown being attracted to the high-gradient region near the electrode, initiating an electron avalanche. Electrons are swept into the electrode, leaving positive charges behind as shown at *B* in Fig. 13. These charges effectively extend the electrode potential into the oil, thus shifting the maximum gradient away from the electrode. Concurrently photon electrons are produced by virtue of recombination in the channel, which also produces visible light. The photon electrons are again attracted toward the electrode, causing an extension of the channel. The process then repeats. However, as the channel progresses farther, the maximum gradient decreases in magnitude until it falls below some critical value where further ionization is not possible. This is illustrated at *C* in Fig. 13. All this constitutes a stepped streamer which occurs within 1 microsecond. Such a fast process is not resolvable by the Boys camera. Nevertheless the postulation should be considered reasonable when it is compared with the theory of positive streamer propagation in air,[3] because, up to this point it is difficult to see any appreciable difference, except for magnitudes, between the two mechanisms.

Since there is no pilot streamer to pave the way ahead of the stepped streamer, the stepped advance must depend on the space charge build-up along the channel. Upon examination of the probe oscillograms it is noticed that the probe potential may rise or fall with time between two successive stepped streamers. This indicates migration of charges in the channel away from or toward the probe. It is conceivable that the migration is not uniform along the channel because the arrested streamer channel is not uniformly ionized as seen from the high-speed photographs. Thus it is possible to build up more than one space charge center along the channel as illustrated at *D* in Fig. 13. For clarity, only the net positive charges

are shown. As these space charges build up, electrons will be attracted to them, causing further ionization around them. If a charge center builds up near the channel tip, an extension of the streamer will result. If another charge center occurs in the mid-channel, a branching will result. This is schematically shown at *E* in Fig. 13.

It is now apparent that as long as the gradient near the tips can build up above the critical value for further ionization, the streamer will progress for another step. The whole process then repeats itself. Otherwise it will come to a stop.

In the foregoing explanations of positive and negative creepage, many factors were not considered. Among these were magnitudes of photoionization, effects of the solid insulation, interactions between streamers, and losses of electrons attributable to diffusion and attachments in the liquid and solid structures. Knowledge of these and other factors must come from future work. They are absolutely necessary when one deals with the creepage phenomenon on a quantitative basis.

Conclusions

1. As negative polarity impulse creepage moves over an insulating surface, it propagates in a manner analogous to the propagation of stepped streamers in air similar to natural lightning.

2. Probe measurements indicate that this streamer may carry full-line potential for a considerable distance out over the surface and that this potential rises and falls in a manner explained by the alternate progression of a weak pilot streamer and a brighter stepped streamer through the oil.

3. A positive polarity creepage streamer is shown to propagate by a series of discrete discharges that differ from negative polarity in both modes of propagation and channel potentials.

4. Under the test condition described, the average velocity of propagation for both positive and negative streamers is about 0.1 inch per microsecond.

5. The mechanisms of both positive and negative impulse creepage in oil are postulated in considerable detail.

Appendix. Calculation of Pilot Streamer Characteristics

In Fig. 14, an idealized pilot streamer is sketched. If one assumes that the region surrounding the channel is homogeneous and isotropic, and that the pilot streamer is largely a "minimal" streamer (in that it represents the minimum possible condition for propagation, so that charge density, channel size, and velocity of propagation are minimal), then certain approximate calculations of channel characteristics may be made.

The approximate relationships are

$$q_c = \frac{2\epsilon E_r}{r} \tag{1}$$

$$i_s = q_c K E_s \tag{2}$$

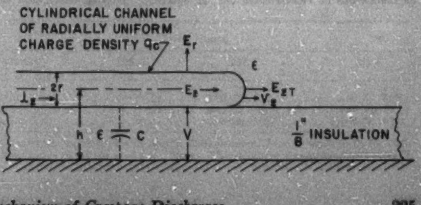
$$R = \frac{1}{2\pi r \epsilon E_r K} \tag{3}$$

$$C = \frac{24}{\log_{10} \dfrac{2h}{r}} \tag{4}$$

$$v_s = K E_{sT} \tag{5}$$

$$V = \frac{\pi r \epsilon E_r \log_{10} \dfrac{2h}{r}\, 10^{12}}{12} \tag{6}$$

where



CYLINDRICAL CHANNEL OF RADIALLY UNIFORM CHARGE DENSITY q_c

ϵ
C
V
$\frac{1}{8}$" INSULATION

Fig. 14. Idealized pilot streamer characteristics and equations

ϵ = dielectric constant of both oil and solid insulation
E_z = axial gradient within the streamer channel
E_{zT} = axial gradient at the streamer tip
v_s = velocity of streamer tip
q_c = channel charge density
i_z = axial current density

Then if the axial gradient along the channel does not vary drastically, and the radial gradient at the channel walls is the critical breakdown gradient of oil, then equation 1, for channel charge density in coulombs per cubic meter can be derived from Gauss' law. For gradients and radii encountered in oil, a charge density of about 10 coulombs per cubic meter (or roughly 6×10^{12} electrons per cubic centimeter) is obtained. This is about 3×10^{3} times the number of electrons postulated by Schonland[8] in the lightning pilot streamer. It is to be expected that in liquids the election density would be much higher.

Equation 2 is the normal conduction equation from which one can derive total pilot streamer channel currents of a few milliamperes, assuming an electron mobility in oil of 10^{-4} meter per second per volt per meter and axial gradients within the channel somewhat less than the critical oil breakdown gradients at the channel tip.

Equation 3 is derived by combining equations 1 and 2, and for small radii it may reach several thousand megohms per meter or tens of megohms per centimeter. Combining this value with the approximate channel capacitance to ground given by equation 4 as possibly 0.5 micromicrofarad per centimeter, one arrives at a channel charging "time constant" of 10 to 50 microseconds per centimeter of length. This approaches the average propagation time of 4 microseconds per centimeter for the breakdown process.

Equation 5 is a simple expression for velocity of electrons at the channel tip, and gives the approximate value of creepage velocity as discussed in the text if the tip gradient E_{zT} is taken as the breakdown gradient of oil.

Equation 6 is derived from the simple relation $V=Q/C$ where Q is derived from equation 1 and C is the approximate expression of equation 4. This expression also predicts the same order of magnitude of potential to ground as that measured by the probes.

◆

Discussion

G. M. L. Sommerman (Westinghouse Electric Corporation, East Pittsburgh, Pa.): By the use of probe electrodes, the authors have added another valuable experimental technique to those previously reported (reference 6 of the paper) for investigating the propagation of impulse streamers over a solid-fluid interface. This permits data to be obtained on streamer propagation velocities (complementing those obtainable from the Boys camera and other photographic means) but mainly it provides data for obtaining information on streamer gradients as a function of time and distance along the streamer. From the last, it is possible to estimate streamer charge distribution and current density as functions of time and distance, as the authors have shown.

In the calculations of streamer current densities as described in the Appendix and Fig. 14, it is evident that assumptions have to be made for the gradients normal to the streamer and for electron mobility in the immersant. The latter is especially difficult to estimate reliably. It is suggested that estimated values of streamer currents and densities could also be obtained from current-time oscillograms for the whole streamer array and an analysis of the photographic record of the array. Such oscillograms were included in the previous paper (see reference 6), but quantitative co-ordinate scales were not reported. It would be helpful if the authors would report in their closing discussion some of these quantitative total streamer-array current values as a function of time.

With respect to the use of long-tailed impulse-voltage waves by the authors, the longer streamer lengths obtained with such waves compared with those for $1\frac{1}{2}\times40$-microsecond waves confirm results obtained by Bute, Larson, and the writer with waves of about ten times the standard tail (reference 4 of the paper). For waves of this type, reference 4 also gives results with waves chopped at various times to permit taking photographic records of streamer formation in liquids as a function of time of application of voltage. Such data, of course, overcome the time-dependence limitation of the simple Lichtenberg-figure or photo-paper technique mentioned by the authors in their second paragraph. The chopped-wave photo-patterns do yield quantitative information of streamer propagation velocities, although they do not give all of the information obtainable from the Boys camera used by the author. The photographic records whether integrated or time-dependent are still our best means for determining streamer densities as a function of spatial co-ordinates in an insulated structure, although, once known, the streamer paths may be evaluated further by the probe technique described in the paper.

J. G. Anderson and **T. W. Liao**: We appreciate Dr. Sommerman's discussion and are happy to see the check between our results and those obtained by Mr. Bute, Mr. Larson and Mr. Sommerman on the wave dependence of streamer lengths.

Dr. Sommerman's suggestion on estimating stepped-streamer currents was tried in our previous investigation (reference 6 of the paper) in which the streamer current oscillograms were presented. However, because of the uncertainty of the amplifier gain and the oscilloscope response for the exceedingly fast streamer pulses, the values of currents were not reported in that paper. A rough estimate, based on a calibration of the measuring circuit with simulated pulses, gave a current of approximately one ampere for a streamer 3 inches long. Somewhat smaller current values were obtained for the shorter stepped-streamers. With these estimated values a current density of about 500 amperes per square inch would be obtained for a stepped-streamer channel of 50-mil diameter. Similar values of stepped-streamer current densities can be obtained by estimating the currents required to charge the channel capacitance to full voltage in the streamer formation time of less than 1 microsecond.

It is difficult to use pulse current amplitudes to compute the pilot-streamer channel characteristics because the pilot appears to propagate continuously. Thus the computations and assumptions of Fig. 14 and the Appendix become necessary.

A Method for Evaluation of Thermal Stability of Magnet Wire Enamel

C. G. CURRIN
ASSOCIATE MEMBER AIEE

J. F. DEXTER
MEMBER AIEE

Synopsis: A method for evaluating the thermal stability of magnet wire enamel has been developed using the dielectric strength of the enamel film as a criterion. This test method was designed for accuracy, simplicity, and economy in time, labor, materials, and equipment. Standard National Electrical Manufacturers Association (NEMA) dielectric strength twists[1] are dipped in an electrical impregnating varnish and used as test samples. To achieve sufficient accuracy, a large number of these twists are included in an enamel evaluation program. The twists are placed in aging ovens at various temperatures. Periodically the samples are removed and tested by applying a high voltage. The average aging time required to reduce the dielectric strength of the twists to a preselected value is considered the life of the enamel. The relative life of the enameled wire insulation system over a wide temperature range may then be predicted from the life of the samples determined at several temperatures. Studies have been made of this test method under different sample preparation methods, failure criteria, and aging conditions. Results determined by this test are compared with motor-aging test results on the same enamel-impregnating varnish insulation systems. This comparison shows that this is a convenient functional test method that can be correlated with the results of a more complicated motor test program.

TESTS are developed to predict the behavior of a material in service. The purpose of the twist-aging test is to predict accurately the life of a magnet wire enamel-impregnating varnish insulation system in service with a minimum expenditure of time, labor, material, and equipment. This is accomplished by using a number of easily constructed samples subjected to accelerated aging and functionally evaluated.[2]

The test is not designed to replace motor or similar functional equipment tests. Instead, it is a laboratory test method designed to screen a variety of insulation systems. A motor or similar aging test program is then used for confirmation of the most desirable system. This permits the use of an inexpensive test method for screening and the more expensive and more accurate tests for final evaluation.

In evaluating this screening test method, the following requirements were considered:

1. Results must have a high correlation with service.
2. Results must have high statistical accuracy.
3. Results must be reproducible.
4. Failure criteria must be functional.
5. Time required for failure must be as short as possible.
6. Application of conditioning must be simple.
7. Number of conditioning factors must be kept to a minimum.
8. Evaluation of samples must require a minimum of time, material, skill, and equipment.
9. Preparation of samples must require a minimum of time, material, skill, and equipment.
10. Samples must be consistently fabricated, replacing skill with tools wherever possible.
11. Test must be responsive only to factors determining the life of an insulation system in service and in the same order of magnitude.

Factors Considered

Two major factors affecting the life of insulating systems are thermal degradation and dielectric fatigue. To simplify the test procedure, dielectric aging has not been included in this test. Other factors such as moisture, chemical contamination, and mechanical vibration usually do not in themselves cause failure of an insulation system, but are factors that result in failure only after the system has been weakened by thermal deterioration.

The test sample is a standard NEMA dielectric strength twist of the enameled wire, reinforced for mechanical strength, identified, and impregnated with an electrical insulating varnish.[1] The samples are aged at several temperatures. The life-temperature relationship is then established over a temperature range. This relationship[3] is the goal of the test and from these data the life at lower temperatures can be predicted.

Since the primary purpose of magnet wire enamel is to serve as a dielectric barrier, the over-all effectiveness of the enamel may be determined from the dielectric properties. Any fault in the dielectric barrier of the enamel film which would cause an apparatus to fail may be detected by a decrease in the dielectric strength of the enamel. Dielectric strength is one dielectric property which is easily measured. This is the functional and practical basis for selecting dielectric strength as a criterion for enamel failure.

For simplicity, the test voltage is applied for only 1 second and is applied periodically during the aging of the twists. When all the samples have failed the test voltage, the average life at the particular aging temperature is determined. The life-temperature characteristic may then be plotted.

Some of the factors of this test method which have been studied are:

1. Sample preparation methods.
2. Effect of varnish impregnation.
3. Effect of thickness of varnish film.
4. Failure criteria.
5. Effect of moisture conditioning.
6. Effect of wire size.
7. Reproducibility of results.
8. Effect of thermal shock.
9. Aging temperatures.
10. Number of samples required.

Studies of these factors were made by

Table I. Modified Silicone Enamel Life Versus Impregnation

Enamel Coated to Heavy Build on No. 18 Copper Wire. Twist Samples Impregnated with One Coat of Varnish. Samples Tested with a Failure Criterion of 2.3 Kv (30% of Original Dielectric Strength)

determining the life-temperature curve of several magnet wire enamels, varying one factor for each test. Polyvinyl formal, a modified silicone enamel, and a synthetic organic enamel were evaluated. Approximately 20 samples were aged at each temperature ranging from 200 to 300 degrees centigrade (C). The samples were periodically removed from the aging ovens and evaluated by being subjected to the test voltage for 1 second. The average life of each group of samples at each temperature was determined as well as the standard deviation and the statistical accuracy[4] of the data. These data are given in Tables I through V. The data were also plotted to determine the life-temperature characteristics for each study. These curves were determined by plotting the average values and constructing the curves for a maximum probability of accuracy. To simplify interpretation of the curves shown, the individual points and their probability limits as given in the tables are not shown.

Sample Preparation Method

The standard NEMA dielectric twist was selected because of its simplicity, low cost, and functionality. Fig. 1 shows the completed test sample. It was found necessary to limit the bending of the leads where they enter the twisted section of the sample. A jig was designed to assure uniform bending of the leads. The spacer between the leads reduces the bending moment on the leads where they enter the twisted section. The spacer reduces mechanical damage to the insulation at this critical spot resulting from the handling of the sample during the aging periods. The spacer also serves as a support for an identifying label on each twist. Spacers must be of a material equal to or better than the wire enamel in thermal stability.

Each twist is impregnated with a suitable electrical varnish. The impregnating varnish is cured at a temperature which has a negligible effect on the wire enamel.

After impregnation, all samples of one test series are grouped together in aluminum radio chassis which are convenient oven trays. These trays are arranged so that the oven air may flow freely over all the samples. Three to 5 minutes are allowed for the samples to reach the aging temperature in forced air ovens.

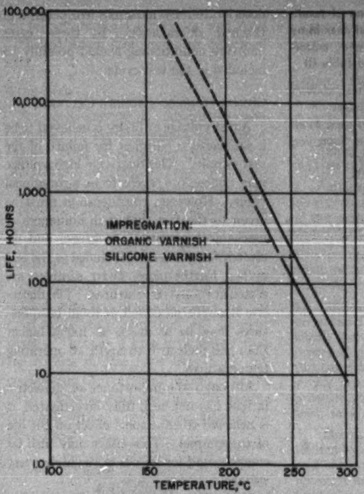

Fig. 2. Effect of impregnation on life of modified silicone enamel. Enamel was coated to heavy build on no. 18 copper wire. Samples were impregnated with one coat of varnish and tested with a failure criterion of 2.3 kv (30% of original dielectric strength). See Table I

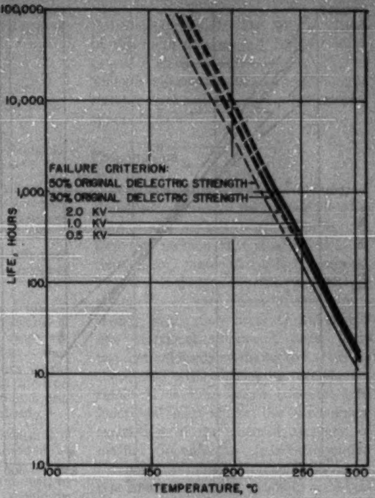

Fig. 3 (right). Effect of failure criterion on life of modified silicone enamel. Enamel was coated to heavy build on no. 18 copper wire and impregnated with one coat of silicone varnish. See Table II

EFFECT OF IMPREGNATION

Evidence has been found to show that the impregnating varnish has a direct effect on the life of a wire enamel. This is perhaps because of the varnish acting as an oxygen barrier, thus affecting the oxidation rate of the wire enamel. The varnish also provides mechanical protection. Because this test method is designed to be functional, the samples are impregnated with a varnish which would normally be used with the enamel. Although this method is primarily a test of the wire enamel, it is more realistic when it includes the effects of the immediate environment, which is the varnish. Fig. 2 shows the effect of two varnishes on one common wire enamel. The curve shows that the life of the enamel is materially affected by the impregnation.

EFFECT OF THICKNESS OF VARNISH FILM

An investigation was made to determine whether the inpregnating varnish thickness has an effect on the enamel life. The life-temperature curve of samples with one dip in varnish was compared with the life of similar samples that were given two dips. There is little difference between the life of the two samples. Although the varnish thickness on the surface of the samples varies from 0.003 inch with one coat to 0.006 inch with two coats, the varnish thickness between the two twisted wires of the sample remains constant.

FAILURE CRITERIA

Another important consideration in any test method is the failure criterion. It should be a functional property that can be accurately and economically measured. Studies were made of failure criteria of two types: a percentage change in dielectric strength, and a predetermined minimum dielectric strength. These studies show that the failure criterion has a significant effect on the test results. Fig. 3 shows the effect of the failure criterion on tests of one wire enamel. With a failure criterion of 50 per cent (%) of the original dielectric strength after impregnation, the test is completed in the shortest time, but the results are not realistic because enamels with a higher initial dielectric strength are tested under more severe conditions.

The testing will be simpler and the criterion will be more functional if the failure criterion is a fixed dielectric strength that takes into account the stresses to which the dielectric barrier is subjected under service conditions. If the dielectric strength selected as a failure criterion is too high, the enamel will be subjected to abnormally severe stresses and the test results will be less accurate. The effects of the failure criterion on the accuracy of the test results are indicated in Table VI. It is apparent that the statistical accuracy of the test results increases as the voltage criterion is decreased.

MOISTURE CONDITIONING

Moisture is an environmental factor that should be considered in any functional test of electrical insulating materials. The effects of moisture conditioning of the twist sample has been investigated. One group of samples was subjected to a humidity cycle during the aging period. Modified silicone-enameled wire samples impregnated with a silicone

varnish were aged at 250 C. The 25 samples were cycled 24 hours at the aging temperature and then 24 hours at 100% relative humidity at 25 C. The samples were tested at 2.0 kv after each aging cycle and the voltage was reapplied 10 minutes after each humidity cycle.

All but 3 of the 25 samples failed after the thermal aging cycle, rather than after the humidity cycle. This indicates that for the insulation tested the humidity cycle was not an important factor in determinging failure points when a relatively high-voltate failure criterion was used. Furthermore, the humidity cycle greatly complicated the test procedure and increased the time required to complete the test. Some materials may be deteriorated by moisture irrespective of thermal degradation. In these cases moisture conditioning should possibly be included in the test cycle.

Conclusions on Failure Criteria

A test voltage of 1.0 kv is believed to be a satisfactory criterion for failure of the test sample. This relatively high voltage may appear too severe to be a functional value. However, consideration must be given to the fact that such influences as mechanical vibration, moisture, and dielectric fatigue are not included in the test cycle. Furthermore, twist samples are tested at room temperatures. The dielectric strength measured at room temperatures may be as much as 100% higher than the dielectric strength at operating temperatures.

Although the importance of dielectric fatigue has not been fully investigated, it is believed to have some effect on the life of the enamel. This effect may also be compensated for by use of the higher test voltage.

The twist-aging test must be sensitive to any physical discontinuities of the enamel film. This requires a voltage stress between the twisted wires greater than the dielectric strength of air with the same electrode spacing. A criterion voltage of 1.0 kv appears to be necessary to overcome the dielectric strength of the air where moisture is not introduced into the test procedure, and to compensate for the elimination of electrical fatigue as a deteriorating influence. Furthermore, data obtained using this value as

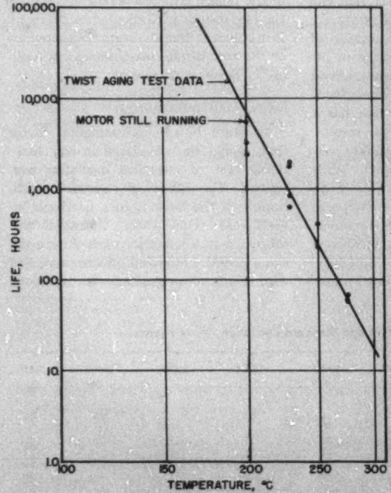

Fig. 5 (left). Comparison of results on modified silicone enamel by twist-aging test and a motor-aging test. Points indicate lives of 10-horsepower 1,200-rpm 3-phase 440-volt 284-frame induction motors. See Table IV

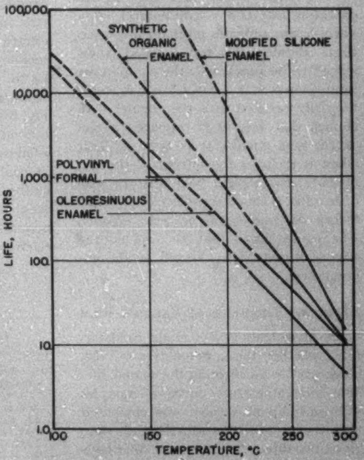
Fig. 6 (right). High-temperature life of various wire enamels. Enamels coated to heavy build on no. 18 copper wire. Samples impregnated with one coat of silicone varnish. Samples tested with a failure criterion of 2.0 kv. See Table V



the failure criterion correlates well with published motor test results as described later.

Wire Size

For convenience in fabricating and handling, the samples should be made of magnet wire of approximately no. 18 American Wire Gauge. Tests of a modified silicone enamel on no. 20 and no. 18 copper wire show no significant difference in resultant enamel life.

Reproducibility

One sample of modified silicone enameled wire was evaluated twice by the twist-aging test, starting at different times. There is a high probability that the results of the tests were identical, considering the statistical accuracy of the data. This is evidence that the results obtained with the twist-aging test can be reproduced.

Thermal Shock

Twist-aging test samples are subjected to thermal shock each time the samples are placed in the ovens and then removed for testing. Tests were conducted to determine the effect, if any, of thermal shock.

A large number of samples of modified silicone-enameled wire were aged at 250 and 300 C. Half the samples at each temperature were subjected to thermal shock similar to other twist-aging tests. The other half were not subjected to thermal shock except for the initial entrance into the oven and removal from the oven for destructive dielectric testing. The dielectric strength of the samples subjected to thermal shock did not vary appreciably from that of the samples not subjected to thermal shock. This was observed during the life of the samples at both aging temperatures. Thus, from this study, thermal shock does not appear greatly to affect the results.

However, an observation made when testing many lots of samples shows some effect of thermal shock. Samples which were not tested during the initial 50% of their life, and were therefore less frequently exposed to thermal shock, had about 10% longer life than samples tested by the standard procedure, which is to test the samples at intervals of 5 to 10% of the expected life throughout the life of the sample. This procedure reduces book work and simplifies the testing of a large number of enamels. Thus, if a prescribed standard procedure is followed, the effect of thermal shock will be constant on all samples; and if the testing intervals deviate from the standard by as much as 50%, then the results may vary approximately 10%.

Aging Temperature

Several principles are involved in selecting aging temperatures:

1. Aging at high temperatures decreases the time required for test completion.

2. Aging at high temperatures where the life is extremely short decreases the accuracy of the test. Results obtained on samples that fail in 20 hours or less are not reliable.

3. Accuracy of the slope of the life-temperature curve is improved as the range of test temperatures is increased.

4. Life expectancy at operating temperatures can be extrapolated most accurately when the lowest aging temperature approaches the operating temperature. Furthermore, lower aging temperatures are desirable because the slope of the life-temperature curve may change with temperature, making extrapolation unreliable.

5. The number of aging temperatures is limited by the practical consideration of the cost of separate oven and control equipment for each aging temperature. However, at least three aging temperatures should be used to determine the life-temperature characteristic of the insulating material.

Number of Samples Necessary

The statistical accuracy of the test is dependent upon the following:

1. The number of samples and the consistency of the failures of each group of samples at each temperature. Ten samples will usually give results of adequate statistical accuracy.

2. Accuracy of temperature control. A tolerance of not more than ±1C is recommended.

3. Range in the aging temperatures.

Correlation of Twist-Aging Data to Motor Test Data

None of the manual operations of the test procedure[5] require any appreciable skill, and thus the test may be performed by unskilled personnel. The twist aging method is of value only if there is close correlation with the results obtained by the more functional motor tests. Motor-aging tests have been recognized as an accurate basis for estimating insulation life.

Fig. 4 shows the correlation between the twist-aging test of polyvinyl formal insulated magnet wire and published motor-aging tests,[6-8] and one coil-aging test.[9] This figure shows that the twist-aging test correlates as closely with the various motor tests as these motor tests correlate with one another. Fig. 5 shows close correlation between the twist-aging test and a motor-aging test[10] on a modified silicone enamel. The data obtained by this method on several different magnet wire enamels are shown in Fig. 6. This curve shows the difference in thermal stability that may be expected of various types of enamel.

Conclusions

The twist-aging test has been designed to predict accurately the service life of a magnet wire enamel by a simple laboratory test method that is economical in time, labor, materials, and equipment. This test is designed for the preliminary evaluation of wire enamels before proceeding to the more accurate and expensive functional equipment tests. This test method has been shown to have close correlation with various motor test results. It is therefore a practical and functional method for the preliminary evaluation of the thermal stability of magnet wire enamels. It is not intended to replace the more comprehensive evaluation of magnet wire enamels in combination with other insulating materials in electric machines.

Discussion

G. M. L. Sommerman (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The repeatability on wire enamel of these life test results, as well as those obtained by other organizations, is very good indeed. This is noteworthy because insulation life results usually show greater deviations as the insulation thickness is decreased to the film forms characteristic of magnet-wire enamel insulation. The accuracy attained is due to the careful planning given to sample preparation, life-test procedures and test criteria which have been contributed by the authors and other workers engaged in such investigations.

In regard to the thermal-aging tests including the high-humidity cycle, it is rather surprising that as many as 88 per cent of the samples tested did not fail after the humidity cycles. Perhaps the humidity, while very close to 100 per cent, was not quite sufficient to cause condensation, which would have permitted free moisture to be drawn by surface-tension forces into any crevices developed in the enamel by thermal aging. It has been suggested that a short water-immersion test might be applied to the samples in lieu of a high-humidity test. This would be relatively simple, less time-consuming, and yet might be more positive than the 24-hour "100-per-cent" humidity test with its inevitable tolerances. In fact, the immersion tests could be run immediately after the dry voltage-withstand tests; also they might be applied to only half the samples tested until experience is obtained with this added feature.

A few preliminary experiments on water-immersed aged enameled wire samples by F. A. Sattler and the writer indicate that this procedure can detect cases where fissures in the enamel walls of the two twisted wires are separated by several times the double enamel thickness. This may be important where equipment is operated at light loads in a cold atmosphere and then brought to a warmer high-humidity atmosphere, especially if voltage transients may be applied to coil terminals.

C. G. Currin and J. F. Dexter: The authors wish to thank Dr. Sommerman for his comments. Following the first presentation of this paper at the 1954 Winter General Meeting, a task force was set up under the sponsorship of the Basic Sciences Subcommittee on Dielectrics to develop a test procedure for the evaluation of the thermal stability of enameled wire. The method described in this paper was selected by the task force and a co-operative test program was started to obtain experience using this method. Six laboratories participated in the program, in which two different types of enameled wire were evaluated. The results obtained by each laboratory agreed very well. Subsequent work by the task force has resulted in a test procedure that has been presented to the AIEE for approval for trial use.

In regard to the question of high relative humidity conditioning versus water immersion, the author's recent work also shows that a low-voltage dielectric test after water immersion will detect cracks and flaws in the enameled films more readily than a high relative humidity conditioning. Dr. Sommerman's suggestions should be considered in any revision of the proposed test procedure for the evaluation of the thermal stability of enameled magnet wire.

Insulation Aging Characteristics as Measured by Shearing Modulus

L. C. WHITMAN
MEMBER AIEE

A. L. SCHEIDELER
ASSOCIATE MEMBER AIEE

Synopsis: A method is described for determining the effect of thermal aging on the shearing modulus of flexible sheet insulations by nondestructive tests using a torsion pendulum technique. The test sample, in tape form, is simple and easily prepared. Shearing modulus of the material is determined with the tape functioning as the stressed element in a simple torsion pendulum. Equipment for sample preparation and testing is inexpensive and compact, allowing investigations of many materials with minimum expense and effort. The data obtained by this method of test are of particular value and interest in determining the effect of time and temperature on an important mechanical property of flexible sheet materials. Since tests may be made as a function of aging on a given sample, the technique is very useful in establishing deterioration rates of the shearing modulus for a given insulation. Data have been obtained upon materials of widely different temperature classifications in order to demonstrate the usefulness of the technique.

NUMEROUS methods have been proposed for determining the thermal aging characteristics of electrical insulations. The rate of change of some mechanical or electrical property of the material as a function of time and temperature is generally utilized in specifying life criteria. The measurements used in evaluating these properties may be placed in two broad categories: destructive tests and nondestructive tests.

Such destructive measurements as dielectric strength, tensile strength, and bursting strength have been of demonstrated value in evaluating the aging characteristics of many materials. Generally, however, large numbers of samples are required and it is difficult to determine deterioration rates accurately since only one test may be made on a single sample.

Such nondestructive electrical measurements as insulation resistance and power factor have been used with some success in thermal aging studies. Owing to the difficulties of measurement little attention has been given to similar tests of a mechanical nature. It may be shown, however, that a simple, nondestructive mechanical test using shearing modulus as a criterion is very useful in the study of flexible sheet insulations. This particular property has not been employed previously since no simple method of measurement had been developed. It is believed, however, that it is of major importance since such a basic characteristic of apparatus as the short-circuit strength is closely allied with insulation shear.[1]

Measurement of Shearing Modulus With the Torsion Pendulum

The shearing modulus (or coefficient of rigidity) of a vertical round wire may be determined quite simply by measuring the period of oscillation of an inertia disk attached to its lower end. The mathematics of such a system are relatively simple and the shearing modulus of any isotropic material that can be drawn or formed into a round rod, wire, or thread may be determined easily. Most insulations, however, are flat, thin sheets or tapes, or laminated sections thereof. If a torsion pendulum is constructed of such material, the restoring force producing oscillation of the inertia disk or bar results from the torque necessary to twist a thin rectangular bar.

This torque may no longer be simply expressed and has been the subject of many investigations. Solutions were proposed as early as 1855 by DeSaint-Venant,[2,3] by Buckley[4] in 1914, and by others, but no complete solution appears to have been published until Timoshenko[5] in 1941. This is abstracted in Appendix I to show the effects considered and is later utilized in relating shearing modulus to torsion pendulum period.

Paper 55-35, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 15, 1954; made available for printing November 16, 1954.

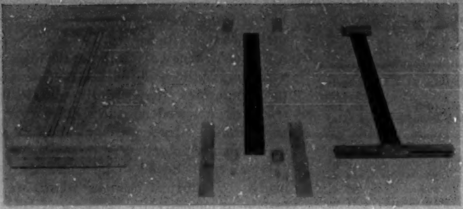

Fig. 1 (left). Torsion pendulum test sample and alignment fixture

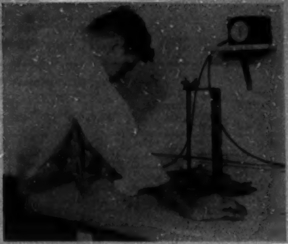

Fig. 4. Test equipment for determining torsion pendulum period

Test Equipment

The equipment for the preparation of samples and testing using the torsion pendulum technique is simple and inexpensive. Except for the aging ovens all the necessary components are illustrated in Figs. 1 through 4. The test piece shown in Fig. 1 consists simply of a suitable length of material (12 inches has proved satisfactory) with metal inertia bars clamped at each end. The inertia bars consist of pairs of steel bars 1 inch by 1/8 inch, the heavier being 6 inches long and the lighter 2 inches long. Note that both sets of these bars are attached to the strip under test and by inverting the test piece either set of inertia bars can be used, the inactive set serving as the top support. Strips of silicone rubber attached to the bars are used to grip the test strip uniformly and to avoid crushing the material.

Care should be taken in assembling the test piece to maintain perpendicularity between the inertia bars and the strip and to have the central axis of the inertia bar coincide with the central axis of the test strip. This may be done by using the simple alignment fixture shown in Fig. 1. A sample rack such as is shown in Fig. 2 is necessary to hold the samples during aging. It is important to give the samples sufficient support to prevent warping or distortion during aging but not to have them under excessive strain. This is accomplished by supporting the strip in a vertical position with a longitudinal stress supplied by the inertia bar. The inertia bar is positioned in slots with small clearance (1/16 inch) to prevent turning or excessive motion due to air currents when aging. It is also important, during aging in the oven, to keep the sample rack level so that no binding or uneven stresses are produced between the top clamping member and the strip.

A timing fixture is necessary which provides true perpendicularity of support for the test piece and some adjustment for minor twisting of the test piece due to aging. The timing fixture shown in Fig. 3 provides an adjustable turntable which may be aligned with the normal relaxed position of the test sample. This relaxed position, rather than the absolute angle referred to top clamp, is taken as the zero angle of twist. The inertia bar is then displaced the specified angle α from this relaxed position and allowed to oscillate. The period of either single or multiple cycles of oscillation may then be timed.

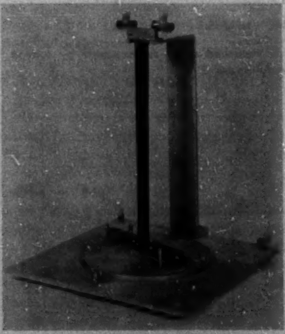

Fig. 3. Timing fixture permitting alignment in relaxed position and indexing of initial angle of twist

Experimental Procedures

Five samples of each material were used at each aging temperature. The period was recorded as the average of five oscillations and five determinations were made for each sample during each measurement. The period was determined before aging, at room temperature and humidity. The samples were then placed in an air recirculating oven and aged at appropriate temperatures. The test pieces were removed from the oven at suitable intervals and measurements of the period were made after cooling for 1 hour at room temperature.

Materials Investigated and Results

The thermal aging characteristics of a number of materials as described in Table I have been investigated using the torsion pendulum technique. The effect of prolonged aging at accelerated temperatures on the period of the pendulums assembled utilizing these materials are illustrated in Table II and Figs. 5, 6, and 7. Tests on black varnished cloth at 175 degrees centigrade (C) and 150 C and on polyethylene terephthalate (My-

lar) at 200 C were terminated when the materials broke during test.

The consistency of results for the black varnished cloth for the different temperatures indicates that orderly chemical reactions are predominantly influencing deterioration. In contrast, the fluctuating results for polyethylene terephthalate (Mylar) are believed to be caused primarily by physical changes which are known to influence the behavior of this material in the region of 150 C. The silicone rubber impregnated glass cloth exhibits much greater stability at 250 C than does the silicone resin treated material.

Nomenclature

a = strip thickness, inches
b = strip width, inches
E = Young's modulus, pounds per inch² (lb/in²)
G = shearing modulus, lb/in²
G_0 = shearing modulus with zero longitudinal stress, lb/in²
G_0^{1} = shearing modulus of unaged strip with zero longitudinal stress, lb/in²
G_0^{11} = shearing modulus for aged strip with zero longitudinal stress, lb/in²
I = moment of inertia of mass, inch-pound-seconds²
I_1 = moment of inertia of lighter pendulum, inch-pound-seconds²
I_2 = moment of inertia of heavier pendulum, inch-pound-seconds²
L = length of suspending strip, inches
M = torque, inch-pounds
m_1 = weight of lighter pendulum, pounds
m_2 = weight of heavier pendulum, pounds
T = time of oscillation, seconds per oscillation
T_0 = period of torsion pendulum with zero weight, seconds
T_1 = period of lighter pendulum, seconds
T_2 = period of heavier pendulum, seconds
U = kinetic energy, inch-pounds
U_0 = kinetic energy for pendulum of zero weight, inch-pounds
U_1 = kinetic energy for lighter pendulum of m_1 weight, inch-pounds
U_2 = kinetic energy for heavier pendulum of m_2 weight, inch-pounds
U_0^{1} = kinetic energy of unaged strip with zero longitudinal stress, inch-pounds
U_0^{11} = kinetic energy for aged strip with zero longitudinal stress, inch-pounds
α = angular deflection, radians per inch length of strip
θ = angular deflection, radians
σ = strip longitudinal stress, lb/in²
$\psi = \alpha$ initial, radians per inch length of strip
ω = angular velocity, radians per second

Torsion Pendulum With Thin Rectangular Strips

The torque produced by the twisting of a thin rectangular strip (where ratio of width to thickness is greater than 100) is shown in equation 29 to be

$$M = \frac{a^3 b G \alpha}{3}\left(1 + \frac{E b^4 \alpha^2}{120 G a^2} + \frac{\sigma b^2}{4 G a^2}\right) \qquad (1)$$

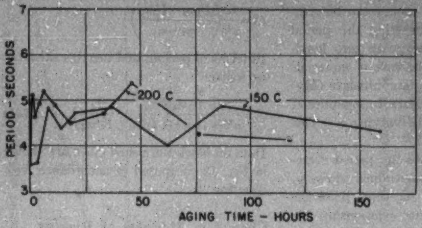

Fig. 7 (left). Mechanical aging characteristics of polyethylene terephthalate (Mylar) as measured by torsion pendulum, using pendulum no. 2

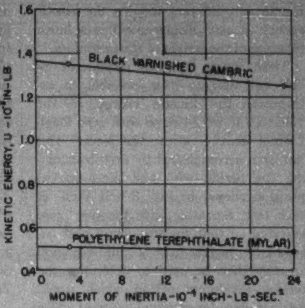

Fig. 8 (right). Kinetic energy of torsion pendulums with constant pendulum weight

This may be rearranged by collecting terms

$$M=\left(\frac{a^3bG}{3}+\frac{ab^3\sigma}{12}\right)\alpha+\left(\frac{E}{G}\right)\frac{ab^5G}{360}\alpha^3 \qquad (2)$$

$$=A\alpha+B\alpha^3 \qquad (3)$$

where

$$A=\frac{a^3bG}{3}+\frac{ab^3\sigma}{12} \qquad (4)$$

$$B=(P)\frac{ab^5G}{360} \qquad (5)$$

$$P=\frac{E}{G}$$

If a mass suspended by the long strip of rectangular cross section is twisted through the angle α and released, the mass will perform oscillatory rotation about the major axis of the strip. Neglecting the mass of the strip and air resistance, and assuming perfect elasticity and no internal friction in the strip, the equation of motion of the mass is

$$\text{(inertia)(acceleration)}+\text{restoring force} = 0 \qquad (6)$$

Since the restoring force is given by equation 3, equation 6 becomes

$$I\left(\frac{d^2L\alpha}{dt^2}\right)+A\alpha+B\alpha^3=0 \qquad (7)$$

or, for a given length

$$\frac{d^2\alpha}{dt^2}+\frac{A\alpha}{IL}+\frac{B\alpha^3}{IL}=0 \qquad (8)$$

This differential equation has the approximate solution[6]

$$\omega^2\cong\frac{A}{IL}+\frac{3}{4}\frac{B}{IL}\psi^2 \qquad (9)$$

Since

$$T=\frac{2\pi}{\omega} \qquad (10)$$

$$T^2=\frac{4\pi^2}{\frac{A}{IL}+\frac{3}{4}\frac{B}{IL}\alpha^2} \qquad (11)$$

Substituting values of A and B from equations 4 and 5

$$\frac{4\pi^2}{T^2}=\frac{4a^3bG+ab^3\sigma}{12IL}+\frac{Pab^5G}{480IL}\alpha^2 \qquad (12)$$

Solving for shearing modulus G

$$G=\frac{1920\pi^2IL-40ab^3T^2\sigma}{160T^2a^3b+T^2Pab^5\alpha^2} \qquad (13)$$

Interpretation of Results in Terms of Shearing Modulus

Certain difficulties are encountered when equation 13 is utilized to interpret the results of Figs. 5, 6, and 7 in terms of shearing modulus G. This expression for shearing modulus contains constants involving dimensions of the strip, dimensions, and weight of the oscillating mass, time of oscillation of the mass, and the quantity P. P is the ratio of Young's modulus E to the modulus of rigidity G, and is of the order of 3 in the initial unaged state for typical insulations. This ratio may change with aging since generally G and E do not change in the same proportions. However, by making α small (15 degrees) it is found that the whole term is a small percentage of the other denominator term and can be neglected with minor error.

Unfortunately the numerator of this expression is the difference of two quantities which are of the same order of magnitude for certain typical dimensions and characteristics of insulations. Thus, the computation of G using this expression is subject to considerable error. It might be expected that using a smaller b (a narrower strip) would help this since it occurs as a cubed term in equation 13. However, decreasing b causes T to increase in about the same proportion, so little is gained. Some improvement is made by making σ smaller if at the same time I is not decreased. This is accomplished by using a mass consisting of long narrow bars. A major improvement may be made in the accuracy of the shearing modulus calculation by obtaining the value of G under the condition of zero applied longitudinal stress. This may be done by considering the energy relations governing the motion of the suspended mass.

Kinetic Energy Relation

Assuming no translatory motion, the kinetic energy of the oscillating mass as it passes through zero displacement is

$$U=\frac{1}{2}I\omega^2 \qquad (14)$$

Assuming that the torsion pendulum executes simple harmonic motion (which is approximately true if displacements are small)

$$\omega^2=\left(\frac{2\pi}{T}\right)^2 \qquad (15)$$

where T = period of pendulum in seconds per oscillation. Hence

$$U=\frac{2\pi^2I}{T^2} \qquad (16)$$

The kinetic energy of the bar should be equal to that energy stored in the tape originally by displacing the bar through the angle ψ. This is verified, in part at least, by the data of Fig. 8 which show that the inertia of the mass has no significant effect on the stored energy calculated from equation 16. This may be confusing, since equation 16 indicates U proportional to I. Note, however, that U is also inversely proportional to T^2 which changes in such a manner with I that the over-all effects cancel out.

It is apparent even from the ideal theory of equation 1 that the energy stored in the test strip will be affected by the longitudinal stress due to the weight of the bar. Test results illustrated in Figs. 9 and 10 show that for torsion pendulums of equal moments of inertia and different weights the kinetic energy at zero displacement is a linear function of the weight of the pendulum.

Thus, using torsion pendulums of different weights it is possible to extrapolate the kinetic energy to the value U_0 it would have with zero longitudinal stress σ on the test piece. This has been accomplished by first determining the period with test piece in the position shown in Fig. 3 and then, at each test, repeating with the test piece inverted so that the top clamp now becomes the inertia bar. U_0 and equation 16 may then be used to determine the torsion pendulum period which would occur if no longitudinal stresses were applied to the test strip. This relation is of great importance and utility since with zero stress σ the term involving σ in equation 13 becomes zero. Thus the calculation of G is more accurate because it no longer involves the difference of two quantities that may be nearly alike. Also, it allows investigation of materials which are so nonisotropic that equation 13 does not give a proper allowance for the influence of longitudinal stresses. For example, the apparent shearing modulus of black varnished cloth as calculated from equation 13 is affected by changing σ; see Fig. 11. This deviation from ideal theory can be compensated for by correcting the period to correspond to that with zero longitudinal stress. In the case of materials such as polyethylene terephthalate (Mylar) equation 13 appears to compute G consistently even with varying σ. This is shown in Table III.

In order to calculate the period corresponding to zero longitudinal stress σ, it is only necessary, for those materials which exhibit a linear relationship between U and σ (as illustrated in Figs. 9 and 10), to compute the y intercept on the curve of weight versus kinetic energy. Then

$$U_0=\frac{U_1m_2-U_2m_1}{m_2-m_1} \tag{17}$$

With σ equal to zero and for small displacement equation 13 becomes

$$G_0=\frac{12\pi^2IL}{T_0^2a^3b} \tag{18}$$

Substituting the value of T from equation 16 with appropriate subscripts and simplifying

$$G_0=\frac{6LU_0}{a^3b} \tag{19}$$

Utilizing equation 17

$$G_0=\frac{6L}{a^3b}\left(\frac{U_1m_2-U_2m_1}{m_2-m_1}\right) \tag{20}$$

In terms of periods and inertias this may be written

$$G_0=\frac{12L\pi^2m_1m_2}{a^3b(m_2-m_1)}\left(\frac{I_1}{T_1^2m_1}-\frac{I_2}{T_2^2m_2}\right) \tag{21}$$

Data on black varnished cloth are shown in Fig. 12 computed in accordance with equation 21.

Change in Modulus of Rigidity With Insulation Aging

Actually of more concern is the change in G rather than its actual value. From equation 19

$$G_0^{1}=\frac{6LU_0^{1}}{a^3b} \tag{22}$$

Also

$$G_0^{11}=\frac{6LU_0^{11}}{a^3b} \tag{23}$$

Then dividing equation 23 by 22

$$\frac{G_0^{11}}{G_0^{1}}=\frac{U_0^{11}}{U_0^{1}} \tag{24}$$

Further Considerations

In some cases there appears to be an effect on pendulum period due to a

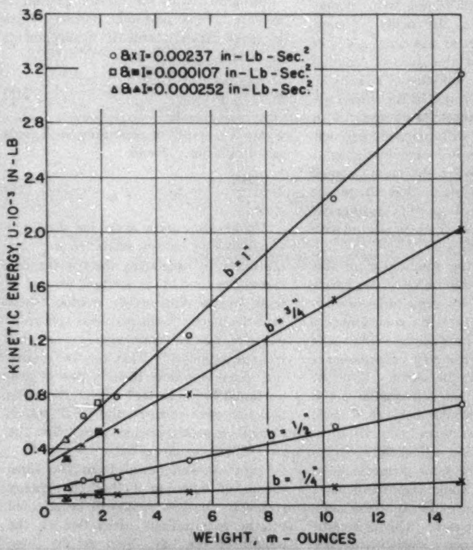

Fig. 9. Kinetic energy of torsion pendulums utilizing black varnished cloth with varying pendulum weight

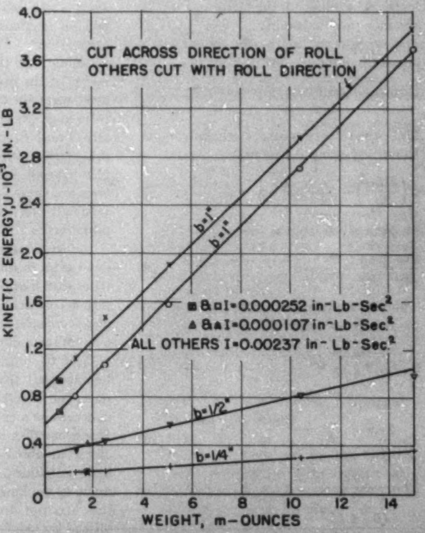

Fig. 10. Kinetic energy of torsion pendulums utilizing polyethylene terephthalate (Mylar) with varying pendulum weight

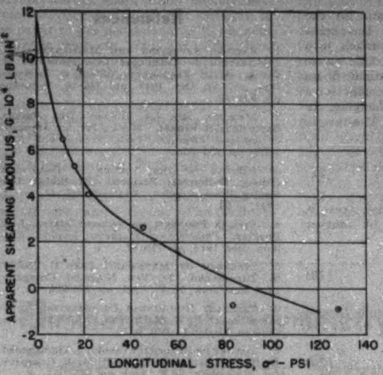

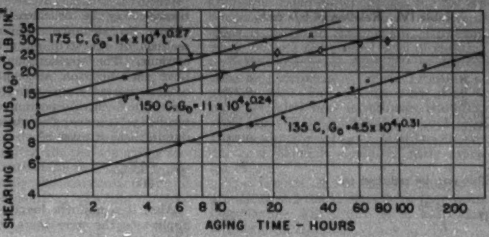

Fig. 11 (left). Effect of varying longitudinal stress with pendulum inertia kept constant

Fig. 12 (above). Shearing modulus for black varnished cloth as affected by aging, calculated from torsion pendulum data

damage of the edge of the material when cutting the sample to width. For example, in the case of black varnished cloth, Fig. 9, the ordinate U_0 is not directly proportional to b as specified in equation 19. However, if a constant amount is deducted from the quantity b to allow for this damage, reasonably consistent results for various widths are obtained. Some other materials such as polyethylene terephthalate (Mylar) show little or no edge effect; see Table III. It thus appears wise to use tapes not less than 1 inch wide to minimize this effect.

In some materials there is an effect on pendulum period due to the direction of cutting as referred to the roll from which the sample is taken. This goes back to the method of manufacture, fiber orientation, etc. An illustration is given in Fig. 10 where samples were cut at right angles to each other. It is thus necessary to be consistent in sampling or else investigate separately the variations encountered.

There may be some effect of ambient conditions on the pendulum period. This has not been fully investigated but it may be desirable to cool for a time in excess of 1 hour and test samples in a room with controlled temperature and humidity.

Deterioration Rates

The orderly changes in the shearing modulus as a function of aging time indicate that this test procedure may prove useful in the study of mechanical deterioration rate phenomena. Data on black varnished cloth at 135, 150, and 175 C (see Table II) show that over a significant portion of insulation life the material exhibits a linear relation between shearing modulus, as calculated by the use of equation 21, and a fractional power of the aging time, as in Fig. 12. The highest values of G_0 shown were obtained with the material in a very brittle and therefore failing condition. It should be noted that the rate of change of G_0 with time is greater for higher temperatures.

The initial variation in torsion pendulum period and consequently in G_0, indicates the desirability of preconditioning at a temperature of the order of 100 C for several hours to give consistent data at initial conditions. It may also be important to be sure of stable measuring conditions by cooling a sufficient time under controlled temperature and humidity.

Table III. Shearing Modulus for Polyethylene Terephthalate

Nominal Thickness 8 Mils

Moment of Inertia, I(10^{-4} Inch-Pound-Seconds^2)	Weight, Ounces	σ, Lb/In^2	Width, Inches	Period T, Seconds	Modulus G(10^5 Lb/In^2)
2.524	0.6094	4.88	1	1.56	2.54
1.074	1.828	14.65	1	0.94	2.66
23.8	5.06	39.6	1	3.76	2.73
2.524	0.6094	9.77	1/2	2.46	2.38
1.075	1.828	29.29	1/2	1.54	2.39
23.8	5.06	79.2	1/2	6.68	2.16
2.524	0.6094	19.53	1/4	3.44	2.50
1.075	1.828	58.59	1/4	2.18	2.56
23.8	5.06	162.18	1/4	9.80	2.46
3.065	4.97	159.29	1/4	3.44	2.69

It is recognized that additional work is necessary, in order to investigate more fully extraneous effects, before data such as in Table II can be profitably analyzed to show the true interrelation of time and temperature on shearing modulus. The data are presented in order to show the basic methods of analysis and computation rather than final results, in the hope that other investigators will be encouraged to attack the insulation aging problem by this new and intriguing technique.

Conclusions

1. A new method has been developed for determining the shearing modulus of flexible sheet materials.

2. This torsion pendulum technique provides a nondestructive method for determining significant mechanical aging characteristics of flexible sheet materials.

3. This procedure should be useful in establishing the deterioration rates of an important mechanical property of various sheet materials.

4. This method offers a means of investigating the co-ordination of mechanical and electrical deterioration rates of sheet insulation materials.

Appendix I. Torque for Thin Rectangular Strips

The equation relating torque to angle of twist for a rectangular strip in such a material as steel is given by Timoshenko[7] as

$$M=\frac{G\theta a^3 b}{3L}\left[1-\frac{192\,a}{\pi^5 b}\sum_{n=1,3,5,\ldots}^{\infty}\frac{\tanh}{n^5}\left(\frac{n\pi b}{2a}\right)\right] \quad (25)$$

Table IV. Relation of b/a to k_1

b/a	k_1
1.0	0.1406
2.0	0.229
5.0	0.291
10.0	0.312
100.0	0.331
∞	0.333

This can be reduced to

$$M=\frac{k_1G\theta a^3b}{L} \tag{26}$$

where k_1 is a numerical factor depending on the ratio b/a. See Table IV.

Equation 26 is very accurate for such material as steel in usual shapes in which the maximum shearing strain during torsion is very small. However, for such a material as rubber and electrical insulating materials, or even very thin strips of steel, the maximum shearing strains during torsion may be considerable and so the change in distance between the cross sections of the strip must be taken into account. The stresses due to this cause have the direction of longitudinal fibers of the twisted strip and are compressive near the central portion, changing to tensile stresses near the edges. The torque due to these stresses is[5]

$$M=\frac{Eab^5}{360}\theta^3 \tag{27}$$

Also, if a uniform longitudinal stress is applied to the strip there will be another added torque[4,5]

$$M=\frac{\sigma\theta ab^3}{12} \tag{28}$$

Combining equations 25 through 28 and assuming $b/a>100$

$$M=\frac{a^3bG\theta}{3L}\left(1+\frac{Eb^4\theta^2}{120Ga^2}+\frac{\sigma b^2}{4Ga^2}\right) \tag{29}$$

◆

Discussion

G. A. Cypher (General Electric Company, West Lynn, Mass.): The authors have presented an interesting and valuable method for following the thermal degradation of a mechanical property of insulating sheet materials. The nondestructive nature of the test and its applicability to nonisotropic materials make it especially useful. The physical condition of materials like impregnated glass fabric after heat aging has been difficult to assess because of the strength and stability of the inorganic fabric. The condition of the organic or silicone treating material, most important from the electrical point of view, may be determined by this torsion pendulum technique.

The electrical properties of some of the materials mentioned in this paper have been studied as a function of time and temperature. The authors' comments would be appreciated on any possible relationship which may exist between some electrical characteristic as a function of aging and these values of shearing modulus as a function of aging.

R. C. Bartlett (Natvar Corporation, Woodbridge, N. J.): The authors deserve a word of commendation, since their testing procedure is uniquely different from any used so far for measuring thermal stability of insulation.

Although most of the data presented indicates that this measurement of embrittlement of insulation by a shearing modulus test is adequately quantitative, the ethylene-glycol terephthalate polyester film (Mylar) gives test values that are outstandingly more qualitative in nature. It is suggested that these more erratic results obtained with this polyester film could be explained by the relaxation of orientation in this film. Heating at 150 and 200 C might cause dimensional changes that would affect the period of oscillation and calculated shearing modulus. Although little information on thermal relaxation and accompanying dimensional changes of such polyester film has been published, an investigation of this might shed some light on the erratic results obtained.

It is well known that thickness of insulation will change during heat aging. Some data of this kind have been given previously.[1] Since the equation given to calculate shearing modulus includes a thickness dimension of the test specimen, it would aid evaluation of this test procedure to know whether progressive change in specimen thickness was considered in the data presented. This point has not been made clear in this paper, and it might be worth considering thickness change in insulation if the authors have not already done so.

The authors have given an opinion on significance of such shearing modulus data when they say, "The silicone rubber-impregnated glass cloth exhibits much greater stability at 250 C than does the silicone resin treated material." It is true that initial changes in the oscillation period of the silicone-varnished glass cloth are much greater than for the silicone rubber-coated fabric. No doubt the authors have based their statement on this fact. However, it is worth noting that after 200 hours of accelerated aging slope of both the silicone varnish and silicone rubber insulation in the oscillation period versus aging time curves are nearly the same. Since the longer term data indicate nearly similar decay rates, I should like to suggest that the thermal stability of both these insulations is substantially the same.

I trust these comments will aid the understanding and use of the shearing modulus test method and data presented by the authors.

Reference

1. Thermal Stability of Insulating Fabrics, R. C. Bartlett. *Publication No. 161*, American Society for Testing Materials, Philadelphia, Pa.

L. C. Whitman and A. L. Scheideler: Dr. Cypher has brought out a very important point in the utility of the torsion pendulum technique in assessing mechanical characteristics of materials having a base material like glass fabric. Such materials maintain a major portion of their mechanical strength in tension irrespective of aging and the consequent deterioration of the impregnant. Thus tensile tests do not provide a good criterion of aging for such materials. The shearing modulus as tested by the torsion pendulum technique, however, does test the mechanical condition of the impregnant. It is this impregnant that is important as far as electrical characteristics of the insulating material are concerned. Thus, the shearing modulus as measured by the torsion pendulum can logically be expected to correlate with electrical characteristics. The authors are, however, accumulating additional data on a variety of materials and expect to report on this information at a later date.

Mr. Bartlett suggests that the somewhat erratic results obtained using polyethylene terephthalate film (Mylar) are due to relaxation of orientation in this film, together with dimensional changes. There were noticeable changes in length during aging, these changes also being of an irregular nature. It should be emphasized that the pendulum periods were at all times repeatable within an accuracy of about 2 per cent so that the large erratic changes shown are not due to to experimental variations but reflect actual changes in characteristics, as Mr. Bartlett suggests.

The initial thickness measurement was used in the calculation of shearing modulus in the data shown. Using actual thickness at each test is of course more nearly correct and in the case of large thickness changes will alter results, especially since thickness as a cubed term. Inclusion of this effect will tend to increase the calculated shearing moduli as aging time increases and even probably to a greater extent at the higher temperatures. Thus decreases in thickness of the order of 10 per cent will increase the calculated shearing moduli in the order of 27%. In the case of black varnished cambric at 150 C the change in shearing modulus for 40 hours would be increased from the value of 265 per cent as shown in the paper to 340 per cent for a 10 per cent change in thickness. It is not evident how this will affect the shape of the aging curve. Inclusion of this effect, however, does make the shearing modulus criterion even more sensitive. We are indebted to Mr. Bartlett in pointing out this considerable effect.

In regard to the comparison of silicone resin and silicone rubber on a glass cloth base, it is evident that while these particular test samples initially had approximately the same period that their initial shearing moduli were quite different. The thickness of the silicone resin-glass sample was one-half that of the silicone rubber-glass sample (see Table I). Hence the initial shearing modulus of the silicone resin-glass would be of the order of eight times that of the silicone rubber-glass sample. After 700 hours the periods were in the ratio of 3.5 to 5.0. Since shearing modulus under zero longitudinal stress conditions is inversely proportional to period squared, this 8-to-1 ratio would be reduced by a factor of the square of the ratio of the periods giving an over-all result of about 3.9 to 1, so that both initially and finally this particular silicone rubber-glass combination had a considerable edge on the silicone resin-glass as far as flexibility is concerned. It is true that, after some rapid initial changes and for the temperatures and times shown, the rate of aging appears to be similar. However, when we note the general level of shearing modulus (and hence flexibility or brittleness) as approximated in the foregoing it appears that the silicone resin-glass is probably fairly near its ultimate condition while the silicone-rubber-glass would seem to have a long way to go. Only longer tests on these materials would definitely establish this.

The interest shown in this method is gratifying and the authors hope that other investigators will utilize it in evaluating flexible sheet materials.

Elimination of Asymmetry Zero-Drift Errors in Magnetic Servo Amplifiers

W. A. GEYGER
MEMBER AIEE

Synopsis: When applying magnetic amplifiers to position-indicating synchro-transmission systems, achievement of an extremely small zero drift is of paramount importance. It is well known that zero-drift errors caused by actual deviations from perfect symmetry of the saturable-reactor and rectifier components of magnetic-amplifier push-pull circuits may be reduced to certain specified values by using proper testing procedures for grading and matching of these components. However, limitation of such errors to sufficiently small values still represents a difficult problem in the design and production of high-performance magnetic servo amplifiers. Application of 2-phase induction motors in connection with special circuit arrangements offers the possible elimination of asymmetry zero-drift errors by supplying the magnetic-amplifier circuit from a magnetic frequency multiplier producing an exact multiple of the frequency of the a-c line feeding directly both the line phase of the motor and the synchro generator of the error-detecting system. In this case, even with nonsymmetrical characteristics of the saturable-reactor and rectifier components, operation of the motor under no-signal conditions will be inherently independent of changes in magnitude and frequency of the a-c line voltage, changes in ambient temperature, etc., with regard to the magnetic amplifier. Application of a higher frequency carrier for supplying the magnetic servo amplifier offers other advantages: its operation becomes more efficient and its speed of response is correspondingly increased. Actually, the possibility of using smaller sized saturable-reactor elements may compensate somewhat for the necessity of additional components of the magnetic frequency multiplier.

WHEN applying magnetic servo amplifiers to position-indicating synchro-transmission systems, the amplifier is supposed to have no output, if its input voltage is zero as a result of exact coincidence of alignment between the control-transformer rotor and the synchro generator rotor, and it is required that fulfillment of this condition be independent of changes in magnitude and frequency of the a-c line voltage, changes in ambient temperature, etc.

The conventional way of applying magnetic amplifiers of the balance detector type[1] to position-indicating synchro-transmission systems consists in operating the magnetic-amplifier push-pull circuit directly from the same 60-cycle or 400-cycle power source from which the synchro system is operated, connecting the input of the amplifier to the synchro-control transformer, and controlling a 2-phase induction-type reversible motor, geared to the control transformer, with the output of the amplifier. The control transformer furnishes an a-c signal voltage, the magnitude of which is an indication of the size of the angular error between control-transformer rotor and synchro-generator rotor, while its polarity or phase is an indication of the direction of the error. Thus, the synchro control transformer performing the function of the differential element of the error-detecting system serves to compare actual angular positions of the input and putput members of the system.

Since the magnetic amplifier is directly connected with the a-c line feeding the line phase of the motor, any undesired output caused by zero-drift errors of the amplifier itself will cause the motor to operate exactly in the same way as does the desired signal-proportional output. Thus, the 2-phase motor, when operated in this way, is unable to discriminate between error-signal output and zero-drift output of the magnetic amplifier.

The Asymmetry Zero-Drift Problem

Magnetic-amplifier push-pull circuits,[2] as used with synchro systems, represent symmetrical a-c bridge networks containing saturable core reactors and dry-disk rectifiers. With perfect symmetry of the saturable-reactor and rectifier components, the aforementioned condition, i.e., the balance condition of the a-c bridge network, will be fulfilled, even when changes in power supply voltage frequency, and ambient temperature occur.

In practice, however, some deviations from perfect symmetry will always exist, because respective characteristics of the saturable-reactor and rectifier elements will never be perfectly identical. Therefore, with zero input, a certain comparatively small output corresponding to the actual amount of asymmetry will be produced. This output, the "asymmetry zero-drift error" of the magnetic amplifier, should be as small as possible.

It is well known that zero-drift errors caused by actual deviations from perfect symmetry of the saturable-reactor and rectifier components may be reduced to certain specified values by using proper testing procedures for the grading and matching of these components. However, the limitation of such errors to sufficiently small values still represents a difficult problem in the design and pro-

duction of high-performance magnetic servo amplifiers.

Elimination of Asymmetry Zero-Drift Errors

An obvious way of eliminating zero-drift errors in magnetic servo amplifiers consists in operating the magnetic-amplifier push-pull circuit as a real a-c amplifier from a separate, higher frequency power source and feeding both the line phase of the 2-phase motor and the synchro generator of the error-detecting system from the 60-cycle or 400-cycle a-c line. This method, of course, makes it necessary to use an additional higher frequency power source, which is generally not available. However, it may be possible in some cases, e.g., in feeding both the line phase of the motor and the synchro generator from the 60-cycle line, whereas the magnetic amplifier will be operated from a 400-cycle power source.

Application of special circuit arrangements, as described in this paper, offers the possibility of eliminating asymmetry zero-drift errors by supplying the magnetic-amplifier push-pull circuit from a magnetic frequency multiplier producing an exact multiple of the frequency of the 60-cycle or 400-cycle a-c line, feeding directly both the line phase of the motor and the synchro generator.

When applying this special method of magnetic-amplifier operation, the output-circuit elements of the amplifier will carry alternating and/or unidirectional currents, the frequency of which is a multiple of the fundamental frequency of the a-c line voltage. For example, when employing a 400/1,200-cycle magnetic frequency tripler for this purpose, a carrier frequency of 1,200 or 2,400 cycles per second (cps) is applied to the output-circuit elements of the magnetic amplifier, while the line phase of the motor and the synchro generator are directly supplied from the 400-cycle line. Therefore, the 400-cycle signal voltage of the synchro control transformer is used for modulating the 1,200-cycle output current of the magnetic amplifier which does feed the control phase of the motor. Thus, in this case, the magnetic amplifier operates as a real a-c amplifier with a carrier frequency $f_c = 1{,}200$ cps, a modulating frequency $f_m = 400$ cps (which is in turn modulated at the signal frequency), and the frequency ratio $f_c/f_m = 3$. This is in contrast to the conventional techniques using the frequency ratio $f_c/f_m = 1$.

It is interesting to note that in this special case of a nulling device it has proved possible to apply the unusually low frequency ratio $f_c/f_m = 3$. This is in contrast to conventional modulation applications where f_c/f_m should be at least 7 to 10.

When applying this special combination of magnetic servo amplifier, 2-phase motor, and magnetic frequency tripler, any undesired output caused by zero-drift errors of the amplifier itself consists of a 1,200-cycle or 2,400-cycle, and a direct current flowing in the control phase of the motor. This current, of course, will not operate the motor (provided that any fundamental component in the carrier does not affect the output of the amplifier), the line phase of which is carrying a 400-cycle current. However, the desired signal-proportional 400-cycle output current of the amplifier will efficiently operate the motor in the usual way. Thus, in this case, the 2-phase motor is able to discriminate between amplifier output values due to application of 400-cycle error voltage from the synchro control transformer and those 1,200-cycle or 2,400-cycle and direct current amplifier output values which may be caused by zero-drift errors produced by actual deviations from perfect symmetry of the saturable-reactor and rectifier components of the magnetic amplifier.

In this way, asymmetry zero-drift errors will be eliminated and, even with nonsymmetrical characteristics of these components, operation of the motor under no-signal conditions will be inherently independent of changes in magnitude and frequency of the a-c line voltage, changes in ambient temperature, etc., with regard to the magnetic amplifier.

Also, of course, application of a higher frequency carrier for supplying the magnetic servo amplifier offers other important advantages in so far as the operation of this amplifier becomes more efficient and as its speed of response is correspondingly increased. Actually, the possibility of using smaller sized saturable-reactor elements may to a certain extent offer some compensation for the necessity of providing the additional components of the magnetic frequency multiplier. Furthermore, it may be stressed that magnetic amplifiers and magnetic frequency multipliers have almost unlimited life. Thus, it is possible to seal both these components hermetically in a single compact case.

At this point it is to be noted that the use of magnetic frequency multipliers in connection with magnetic amplifiers to decrease the size of the saturable-reactor elements and to increase the speed of response was suggested many years ago.[3] This paper, however, deals particularly with the application of special circuit arrangements with magnetic servo amplifier, magnetic frequency multiplier, and 2-phase motor to position-indicating synchro-transmission systems to eliminate asymmetry zero-drift errors of the magnetic amplifier.

The numerous possibilities for applying this special method of magnetic-amplifier operation may be illustrated by a typical example of a practical circuit arrangement which has proved that it can give excellent results when used in connection with instrument-type servos.

Position-Indicating Synchro-Transmission System with 2-Phase Motor, 2-Stage Half-Wave Magnetic Servo Amplifier, and Magnetic Frequency Tripler

The preference expressed for half-wave types of multistage magnetic servo amplifier circuits[4,5] spurred development work on such circuits to be used in connection with various single-phase and 3-phase types of magnetic frequency multiplier circuits, both for line frequencies of 60 and 400 cps.

Fig. 1 shows schematically such a system that will be operated, e.g., from an a-c line with $E_P = 115$ volts, $f_P = 400$ cps, in connection with a 400/1,200-cycle, single-phase, or 3-phase tripler circuit.

In accordance with the basic principle of eliminating asymmetry zero-drift errors, the magnetic-amplifier circuit is connected with the 1,200-cycle output of the magnetic frequency tripler, the 400-cycle input of which is supplied from the 115 volts, 400-cps, a-c line feeding directly both the line phase W_P (with series capacitor C_P) of the 2-phase motor, and the rotor winding R_1R_2 of the synchro generator. The stator windings $S_1S_2S_3$ of the synchro generator are connected with those of the synchro control transformer, the rotor winding R_1R_2 of which is connected with the input of the amplifier. The control phase W_L of the 2-phase motor, geared to the control transformer, is supplied from the output stage of the amplifier with phase-reversible output current I_L.

Output stage and input stage of the half-wave push-pull magnetic-amplifier circuit, preferably having saturable-reactor elements with Orthonol[6–8] tape cores, are coupled by means of differential control windings, N_C' and N_C''. The graphic symbols of Fig. 1, which can be used in a general way for illustrating the actual mode of operation of magnetic-amplifier circuits,[3] show that the black rectifiers D_A' and D_A'' are conducting simultaneously during the first half-cycle period of 1,200-cycle supply voltage, E_M (black polarities), while the white rectifiers D_D' and D_D'' conduct simultaneously during the second half-cycle period of E_M (white polarities). Thus, the output-stage circuit is supplied with unidirectional currents I_A' and I_A'' (black half-cycle pulses), whereas the input-stage circuit carries the unidirectional currents I_D' and I_D'' (white half-cycle pulses), so that the cores of the output-stage circuit are controlled differentially by means of input-stage currents I_D' and I_D'' during the "reset" half-cycle periods.

It is to be noted that the frequency of the a-c components of unidirectional currents I_A' and I_A'', and I_D' and I_D'', is 1,200 cps. Therefore, any 1,200-cycle output caused by asymmetry zero-drift errors of the magnetic amplifier itself will not operate the 2-phase motor, the line phase W_P of which is carrying 400-cycle current ${}_P$. However, when a 400-cycle error-signal voltage E_S is applied to the control circuit $N_S'N_S''R_S$ of the input stage, then currents I_A' and I_A'', flowing through the differential primary windings N_1' and N_1'' of output transformer T_L, will be modulated with 400 cps, and a properly phased 400-cycle output current I_L, flowing through the control phase W_L, will operate the motor in the usual way. Nearly sinusoidal wave shape of output current I_L is obtained as a result of the demodulating effect of a properly rated capacitor C_L connected across the secondary winding N_2 of output transformer T_L.

When the angular position α_G of the synchro generator is exactly coincident with the angular position α_{CT} of the synchro control transformer, there will be no error-signal voltage E_S, output current I_L will be zero, and the motor will remain at rest. However, if the controlling input member M_α, mechanically coupled with the synchro generator, is displaced from its original position, then an error-signal voltage E_S will energize the amplifier, the output current I_L of which will cause the motor to operate in the proper direction to bring the rotor of the synchro control transformer in alignment with the rotor of the synchro generator.

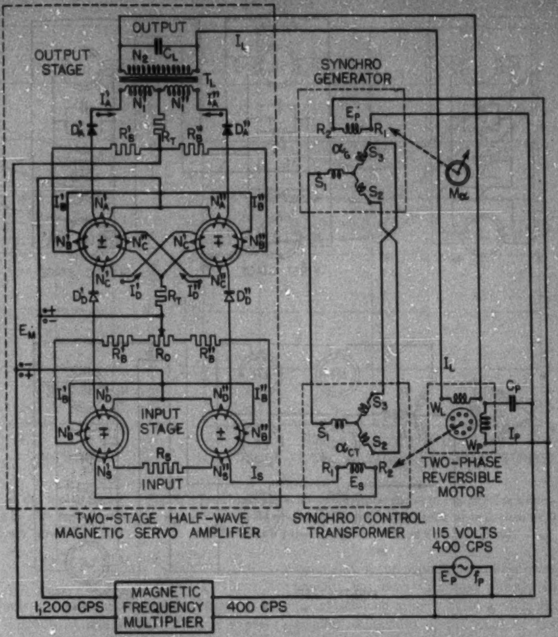

Fig. 1. Position-indicating synchro-transmission system, the 2-phase motor of which is operated by special combination of 2-stage half-wave magnetic servo amplifier and magnetic frequency multiplier to eliminate asymmetry zero-drift errors of amplifier

Magnetic Frequency Multiplier Circuits

The basic principle of magnetic frequency multipliers, sometimes called "static frequency transformers" or "harmonic generators," consists in producing higher harmonics of the power-supply frequency by saturation of magnetic cores, and eliminating the fundamental component and other undesired components by means of bridge and/or filter circuits.

Various single-phase and polyphase types of magnetic frequency multipliers containing saturable reactors, linear reactors, filter circuits and also, in some cases, rectifiers, have been devised by early investigators in the field of radio engineering.[9] Such circuit arrangements with the use of either "sinusoidal excitation" or "shock excitation" were applied many years ago for supplying ink-recording frequency meters[10] and a-c bridge and potentiometer networks.[11] Some magnetic frequency multiplier circuits, proved suitable for supplying magnetic amplifiers, have been described recently.[12–14]

It has been stressed that the fundamental component of the output voltage of the magnetic frequency multiplier should be sufficiently small not to affect the output of the magnetic amplifier. Results of measurements, to be described, have shown that fundamental component distortions in the order of 5 to 10 per cent (%) have no appreciable effect with regard to elimination of asymmetry zero-drift errors caused by very large deviations from perfect symmetry of the saturable-reactor and rectifier components of the magnetic-amplifier circuit of Fig. 1.

Single-Phase Circuits

Fig. 2(A) shows a circuit diagram of a simple single-phase bridge-type[15] magnetic frequency tripler representing a modification of the first transformer-type arrangement[16]. Each of the windings of the saturable reactor *SR* and linear (air-gap) reactor *LR* is divided into two equally rated parts which are insulated from each other; and a properly tuned tank circuit L_TC_T is connected across the load. This tripler circuit, when carefully designed, operates with an efficiency

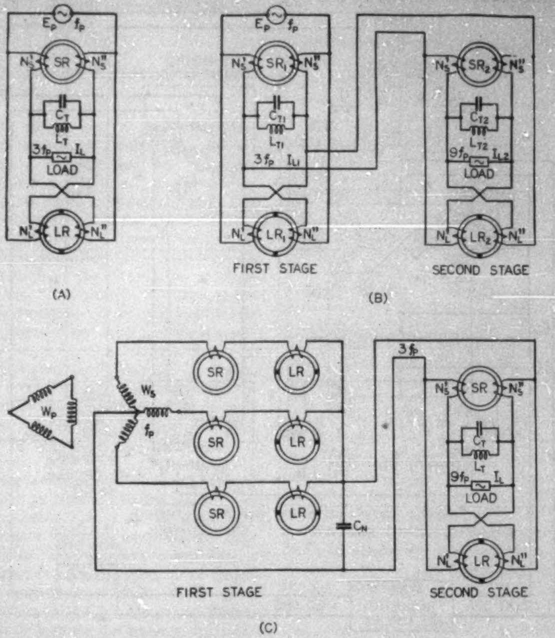

Fig. 2. Magnetic frequency multipliers to be used in connection with the arrangement of Fig. 1

A—Single-phase bridge-type frequency tripler
B—Two-stage bridge-type frequency multiplier
C—Two-stage frequency multiplier, which is a combination of 3-phase input-stage tripler and single-phase output-stage tripler

of about 70 to 80% and will provide a nearly sinusoidal output voltage, the fundamental component distortion being in the order of 5 to 10%.

It is also possible to employ a 2-stage arrangement,[13] Fig. 2(B), each stage consisting of a bridge network with a saturable reactor, a linear reactor, and a properly tuned tank circuit. This arrangement makes it possible, e.g., to convert an input power of 60 cps into an output power of $3\times3\times60=540$ cps with satisfactory efficiency (about 50 to 60%).

Three-Phase Circuits

Another possibility consists in applying the conventional method of producing third-harmonic frequency power by means of three identical saturable-core transformers[18] with wye-connected primary windings and open-Δ-connected secondary windings; and a properly rated capacitor in the secondary circuit may be used to improve the performance of this arrangement.[19]

Fig. 2(C) shows a circuit diagram of a 2-stage 60/540-cycle or 400/3,600-cycle magnetic frequency multiplier, which is a combination of a 3-phase input-stage tripler and a 1-phase output-stage tripler. The output-voltage wave shape of the 3-phase tripler circuit of Fig. 2(C), which may, of course, also be used for single-stage 60/180-cycle or 400/1,200-cycle applications, is purely sinusoidal, provided that the 3-phase loads are perfectly balanced. In this case, total harmonic distortion does not exceed 0.5 to 1%.

Such arrangements,[20] when supplied from a 3-phase, 4-wire power source, contain three wye-connected saturable reactors, *SR*, preferably with series-connected linear reactors *LR*, and a properly rated capacitor C_N; Fig. 2(C), or tank circuit across the load.

In the case of employing a 3-phase, 3-wire power source, a 3-phase transformer with Δ-connected primary windings W_P and Y-connected secondary windings, W_S must be provided, Fig. 2(C), for supplying this type of tripler circuit.

Measurements on Single-Phase Bridge-Type Magnetic Frequency Tripler

Actual performance characteristics of a single-phase, bridge-type, 400/1,200-cycle tripler circuit, Fig. 2(A), may be illustrated by considering results of various measurements on a typical arrangement, designed for a 1,200-cycle maximum output of 50 watts, that is operated from a 115-volt, 400-cycle line voltage in connection with a 2-stage half-wave magnetic amplifier, as shown in Fig. 1.

Dimensions of Components

The saturable reactor *SR* consisted of a spirally wound 2-mil Orthonol[6,7] tape core having the following dimensions: Outer diameter $1^3/_4$ inches; inner diameter $1^1/_4$ inches; tape width 1.0 inch. This core had two multilayer toroidal windings of 135 turns each, of enamel-insulated no. 20 copper wire (Brown and Sharpe gauge).

The linear reactor *LR* consisted of a double-size Permalloy dust core having the following dimensions: Outer diameter 1.85 inches; inner diameter 0.95 inch; total height 1.4 inches. This double core had two multilayer toroidal windings of 160 turns each, of enamel-insulated no. 20 copper wire (Brown and Sharpe gauge).

The linear reactor L_T of the tank circuit consisted also of a double-size Permalloy dust core the dimensions of which were the same as those of the linear reactor *LR*. This double core, however, had two parallel-connected multilayer toroidal windings of 80 turns each, of enamel-insulated no. 18 copper wire (Brown and Sharpe gauge).

Performance Characteristics

Figs. 3 and 4 show 1,200-cycle output voltage $E_L=I_L\times R_L$, and total input current I_P, as a function of 400-cycle line voltage E_P, with capacitance of capacitor C_T of the tank circuit as a parameter (resistive load $R_L=300$ ohms). Similar results were obtained when this resistive load was replaced by the magnetic-amplifier circuit of Fig. 1. Evidently, the regulation of magnitude and frequency of line voltage E_P should be limited to about ±5%.

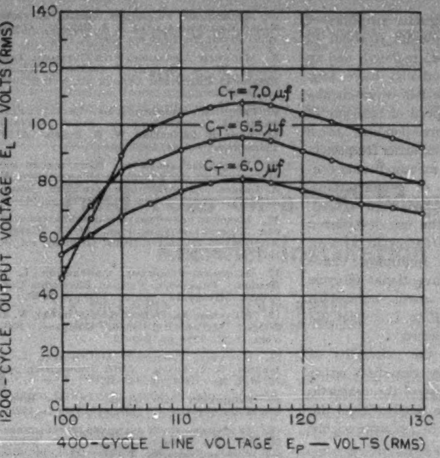

Fig. 3. 1,200-cycle output voltage $E_L = I_L \times R_L'$ of the tripler circuit of Fig. 2(A) as a function of 400-cycle line voltage E_P with capacitance of tank-circuit capacitor C_T as a parameter (resistive load $R_L = 300$ ohms)

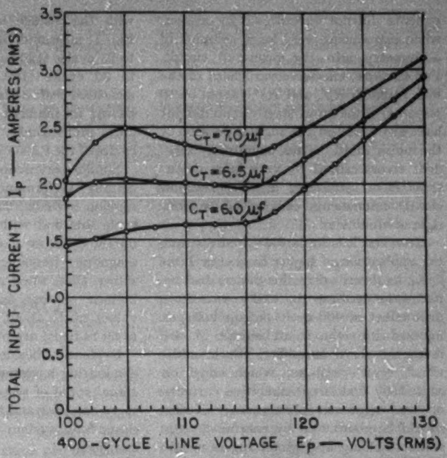

Fig. 4. Total input current I_P of the tripler circuit of Fig. 2(A) as a function of 400-cycle line voltage E_P with capacitance of tank-circuit capacitor C_T as a parameter (resistive load $R_L = 300$ ohms)

MEASUREMENT OF FUNDAMENTAL-COMPONENT DISTORTION

Actual magnitude of the fundamental 400-cycle component E_{400}, of 1,200-cycle output voltage E_L of the tripler circuit, Fig. 2(A), has been measured by applying output voltage E_L to the voltage circuit of a single-phase wattmeter, the current circuit of which was separately excited by means of a sinusoidal 400-cycle auxiliary current I_{400}, as illustrated in Fig. 5.

If the phase shifter is properly adjusted so that the wattmeter shows maximum deflection

$$P_{\max} = E_{400} \times I_{400} \times \cos\theta \qquad (1)$$

$$\theta = \angle(E_{400}, I_{400}) = 0 \qquad (2)$$

then the fundamental component of 1,200-cycle output voltage E_L is given by

$$E_{400} = P_{\max}/I_{400} \qquad (3)$$

and

$$D_{400} = \frac{E_{400}}{E_L} \times 100\% \qquad (4)$$

represents the percentage fundamental component distortion of output voltage E_L of the magnetic frequency multiplier.

This procedure is based upon the simple and convenient method for analyzing the wave shape of alternating currents by means of an electrodynamometer.[21,22]

Fig. 6 shows actual fundamental component distortion of load voltage E_L across the magnetic-amplifier circuit as a function of line voltage E_P. It is evident that magnitude of the fundamental 400-cycle component is about 6 to 8 per cent of the 1,200-cycle load voltage E_L.

Measurements on Closed-Loop Servo System

MEASUREMENT OF ASYMMETRY ZERO-DRIFT ERROR

Actual magnitude of zero-drift errors caused by very large deviations from symmetry of the magnetic-amplifier components has been measured directly in the closed-loop system by observing the angular deflections of the shaft of the 2-phase motor by means of a small mirror and a light beam, as conventionally used in mirror-type galvanometers. This arrangement has been carefully calibrated by injecting an additional 400-cycle signal voltage of 0.50 volt (corresponding to a drift rate of 0.50 degree) into the synchro control transformer circuit. It was found that with the measured fundamental component distortions of about 6 to 8 per cent of 1,200-cycle voltage across the magnetic-amplifier circuit, actual magnitude of zero-drift errors caused by asymmetry of the push-pull circuit com-

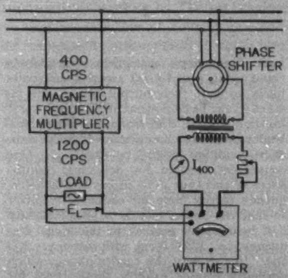

Fig. 5. Measurement of actual magnitude of the fundamental 400-cycle component of 1,200-cycle output voltage E_L of a magnetic frequency multiplier by means of a single-phase wattmeter, separately excited by a sinusoidal 400-cycle auxiliary current I_{400}

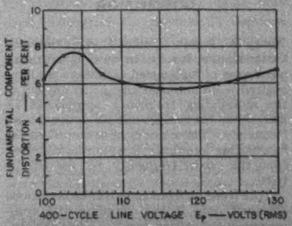

Fig. 6. Percentage fundamental component distortion of frequency-tripler output voltage E_L across the magnetic-amplifier circuit, as measured by means of the wattmeter method of Fig. 5

ponents did not exceed ±1/20 degrees, when introducing very large amounts of asymmetry into the push-pull circuit. For example, excessive variations of the bias resistors R_B' and R_B'' (about ±10 per cent) of the input-stage circuit did not have any effect on the angular position of the motor shaft. Thus, asymmetry zero-drift errors caused by very large deviations from symmetry of the push-pull circuit components can indeed be considered eliminated.

However, it is important to stress that the application of higher frequency ratio f_c/f_m, as described in this paper, does by no means decrease the well-known zero-drift effect of 400-cycle pickup voltages injected into the input circuit of the magnetic servo amplifier. Such additional error voltages, which may be caused by undesired capacitive currents or by unintentional coupling effects, should be eliminated by careful electrostatic shielding and grounding of windings and proper wiring design.[23]

Measurement of Bandwidth of Closed-Loop Servo System

Referring to the dynamic performance of the synchro-transmission system of Fig. 1, it is to be noted that the speed of response of the 2-stage half-wave, push-pull magnetic amplifier is inherently $1^1/_2$ cycles of its power supply frequency.[4,5] When supplying the magnetic servo amplifier with 1,200 cps, instead of 400 cps, actual speed of response will be 1.25 instead of 3.75 milliseconds. Results of various measurements on the closed-loop system using a servoscope arrangement have shown that the bandwidth of the system can be correspondingly increased in this way. For example, with the 2-stage magnetic amplifier of Fig. 1, measured bandwidth is about 19 to 23 cycles (120 to 145 radians), and up to 30 cycles (190 radians) have been measured with 3-stage half-wave circuits having an inherent speed of response of 1.67 milliseconds corresponding to 2 cycles of the 1,200-cycle carrier frequency.

Similar servoscope measurements concerning performance of synchro-transmission systems, supplied from the 60-cycle line and with the use of either a 60/180-cycle or a 60/540-cycle type of magnetic frequency multiplier, have shown that, when conventional 60-cycle 2-phase motors are used, bandwidth values up to about 10 to 11 cycles (63 to 69 radians) are obtained.

Evidently, besides the possibility of eliminating asymmetry zero-drift errors actual speed of response of the magnetic servo amplifier and the bandwidth of the closed-loop system will be appreciably increased.

Discussion

Henry W. Patton (Collins Radio Company, Cedar Rapids, Iowa): In working with various forms of high-speed amplifiers we have noticed a pronounced change in output as the modulating frequency approaches an integral or fractional multiple of the carrier frequency. These are most severe when the modulating frequency is one order different from the carrier frequency, i.e., one-half or twice.

True freedom from zero-drift errors can be obtained only if the "fundamental component in the carrier does not effect the output of the amplifier" as pointed out in the paper. If, however, this does occur, the effects could be minimized by locking the phase of the amplifier carrier to that of the motor supply and adjusting the phase relationships for minimum disturbance. Magnetic frequency multipliers, particularly those using tuned tank circuits, are quite likely to shift their output phase with respect to the basic power supply under varying temperature and frequency conditions. Under these circumstances an effective zero-drift condition might be expected. One convenient method for detecting disturbances of this type is to supply the high-frequency carrier from an oscillator-amplifier so that the carrier can be adjusted slightly "off beat" with respect to the signal frequency, i.e., 1,200.5 cps with respect to 400 cps. In this way the carrier phasor which normally rotates exactly three times for each rotation of the power supply phasor will gain phase slightly each revolution giving rise to a relative phase drift equivalent to 0.5 cps. The resultant interaction on the motor may be readily observed.

Such effects might cause nonlinearities each side of the null particularly considering interaction with the quadrature component found in synchro control transformers. The carrier system described will undoubtedly eliminate the major drift troubles with amplifiers, but we wonder if drift has been observed caused by phase shift as described.

Dr. Geyger is to be complimented on a worth-while contribution which gives us another tool with which to attack two difficult magnetic amplifier problems, time response and drift.

W. A. Geyger: To avoid the difficulties which would arise in the case that the modulating frequency (fm) is one order different from the carrier frequency (fc), i.e., one-half or twice, the magnetic-amplifier system described in the paper does employ a single-phase or 3-phase magnetic frequency tripler or a 2-stage type of magnetic frequency multiplier consisting of triplers connected in cascade for providing the suitable frequency ratio fc/fm = 3 or 9 respectively.

I am grateful to Mr. Patton for stressing that true freedom from asymmetry zero-drift errors can be obtained only if actual magnitude and phase relationship of the fundamental component in the carrier does not affect the output of the magnetic amplifier, as already pointed out in the paper.

Mr. Patton's suggestion of supplying the high-frequency carrier from an oscillator-amplifier so that the carrier can be adjusted slightly "off beat" with respect to the signal frequency offers a convenient method for detecting any disturbances which may be caused by an excessive fundamental-frequency output-voltage component of the magnetic frequency multiplier.

Field Tests on a 100-Megawatt Rectifier Installation

IN THIS paper results are presented from field tests made in March 1954 on the 100-megawatt ignitron rectifier station at the Robert P. Patterson plant, Arkadelphia, Ark., of the Reynolds Metals Company. Power from the rectifier station is used in the electrolytic reduction of aluminum, and all of the power is consumed on one aluminum potline. This is the largest concentration of d-c power on a single potline in this country.

During World War II, a number of rectifier installations were made to provide d-c power in the neighborhood of 60,000 amperes and 650 volts for production of aluminum and other light metals. As more efficient processes for making metal have been developed, there has been a trend toward higher voltages and currents on potlines built since the end of the war. Several potlines in this country now take 72,000 amperes at 750 volts. In January 1954, the 800-volt 125,000-ampere potline on which these tests were made was put in service at Arkadelphia.

The trend toward the use of larger rectifier installations has introduced new problems, principally with respect to switching larger blocks of power and providing for protection against higher arc-back currents. All of the phenomena associated with these problems have not been completely understood because of a lack of field data. These tests were made to obtain the data needed for a better understanding of these phenomena.

A 1-line diagram of the Arkadelphia rectifier station which consists of 24 ignitron rectifier assemblies, two assemblies being connected to each parallel double-wye rectifier transformer, is shown in Fig. 1. Test oscillograms were taken on two 9-element magnetic oscillographs mechanically coupled together, so that it was possible to record two oscillograms simultaneously. Klydonographs were located at strategic points to obtain records of surge overvoltages if any occurred. Both load-switching and fault-clearance tests were made. Since different principles are involved in these two switching operations, this report is divided in two parts: load-switching tests and arc-back tests.

Load-Switching Tests

Power interruptions on rectifier installations may occur either because of involuntary loss of a-c power or because of voluntary shutdowns, the latter often resulting from emergency conditions in the cell room. On older installations, where the maximum current is around 60,000 amperes, voluntary load drops are usually made by master-tripping the cathode circuit breakers. Where this practice is followed on large rectifier installations, load-dropping tests have shown that highly inductive high-current potlines impose severe interrupting duty on d-c circuit breakers.[1] The last breaker to clear must interrupt roughly one-half of the normal potline current[1] which also must be carried by the rectifier tanks and transformer for 1 or 2 cycles. The inherent limitations of dropping load by master-tripping systems were not overcome in those early electrochemical installations where individual a-c circuit breakers were used on each rectifier unit, because the cell line inductance forced high currents to shift to the last rectifier unit to clear, regardless of whether the operation was made by master-tripping the unit a-c breakers or by master-tripping the cathode breakers.

Some rectifier installations were originally set up to drop load by blocking the ignitor circuits to stop firing, but this method was abandoned because excessive overcurrents and arc backs frequently accompanied the switching operation.[1]

If load is dropped by interrupting the a-c supply to the high-voltage bus, and auxiliary power is maintained on the rectifier firing circuits, any anode is free to conduct and the decaying current to the potline may take any path through the d-c winding of the transformer. Current flow is confined to the low leakage inductance path, afforded by two anodes 180 degrees apart, and decays smoothly to zero in each rectifier unit. For this reason, this method of making voluntary trips, both planned and emergency, was recommended for large rectifier installations.[1] This is the method used at Arkadelphia. The purpose of the tests was to substantiate this practice.

TEST PROGRAM

The normal method employed at Arkadelphia for a planned trip of the potline is to run the voltage regulator down, apply roughly a 33-degree delay to the firing circuits, and then trip the three 13.8-kv line circuit breakers with auxiliary power kept on the rectifiers. For emergency trip, the same procedure is followed except the voltage regulator is not moved and no delay is applied. In restoring load following a power interruption, the sequence is to close the a-c line breakers, unshort-circuit the ignitor circuits, remove delay, and run the voltage regulator up to full position.

Tests were made to substantiate these practices for planned and emergency trips and for restoring load. In another test, for comparison, a 42-degree delay was used instead of the normal 33 degrees. Consideration also must be given to those situations where power interruptions result from involuntary loss of a-c power in which cases the source of auxiliary power is lost. Therefore, one additional test

was made by tripping the line circuit breakers and auxiliary power supply, simultaneously, with the voltage regulator in the full position and no delay was applied.

Initial conditions of the potline at the time of each test are tabulated in Table I. Readings were recorded from meters on the operator's control board just before the test. Oscillograms were made on each switching operation. There were not enough oscillographic elements available to record all 24 rectifier assembly cathode currents, but all of the *A* assembly units were recorded as well as potline voltage and voltages on the line side of the 13.8-kv circuit breakers.

RESULTS OF LOAD-DROPPING TESTS

Four load-dropping tests were made; the normal use of the method followed in each test is given in Table I. The oscillograms from test 3 are shown in Fig. 2. Oscillograms for the other tests where auxiliary power was kept on the rectifiers are not included here, because there were no essential differences in the results of the first three tests except in the magnitude of load dropped. The oscillograms from test 4 are shown in Fig. 3. To retain one a-c voltage trace for timing, the phase-1-to-phase-3 voltage was picked up back of the breaker used to drop the auxiliary power source. Maximum cathode currents are tabulated in Table II; these were measured from the oscillograms and are expressed in terms of their switching transient indexes (STI). STI is defined as the ratio of the maximum current after the switching operation to the current before the operation. For example, in test 1, each cathode circuit carried 3,250 amperes, since the load current of 78,000 amperes was divided among 24 cathodes. Thus, a STI of 2.0 in cathode 1*A* indicates that the maximum current transient was 6,500 amperes. This is just a convenient way of saying that this particular current doubled during the transient period.

The 13.8-kv bus at Arkadelphia is sectionalized, see Fig. 1, each of the three sections being supplied through an a-c circuit breaker. When load is to be interrupted, the three a-c breakers are tripped simultaneously, but all of them do not interrupt at exactly the same instant. Looking at the first three tests in Table II, where auxiliary power was maintained, the breaker supplying rectifiers 5, 6, 7, and 8 cleared first and these units immediately gave up their portion of the load to the other eight units. The breaker supplying rectifiers 9, 10, 11, and 12 was the second to clear, and the four units left on tried to hold the load. After a fraction of a cycle, the last circuit breaker cleared. The inductance of the potline prevents the sudden stoppage of current through it, and current trapped in rectifiers at the instant the a-c breakers cleared decayed exponentially to zero. In test 4, auxiliary power was tripped simultaneously with the a-c power supply. Since the auxiliary power source cleared ahead of the last line breaker, some erratic

*The ratio of maximum current following the switching operation to the current before the operation.

shifting of current among rectifiers was observed on this test.

A sectionalized bus arrangement is the most practical way to handle large blocks of power with equipment of reasonable size. The number of sections should be kept at a minimum consistent with practical equipment ratings, however, because of the tendency of current to increase on the last group of rectifiers to drop load. With three sections, as used at this plant, the transient current carried by any rectifier is not excessive.

Comparison of the first three tests of Table II shows that the introduction of delay before tripping the a-c breaker has no effect on the switching transient index. Delay is desirable in planned trips, however, to reduce the magnitude of load which is abruptly dropped from the power system.

Auxiliary power should be maintained when load is dropped on voluntary trips. The basis for this conclusion can be seen better by looking at Figs. 2 and 3 than at Table II; it is a matter of smoothness of current decay since no rectifier was overloaded beyond its short-time rating in either test. Therefore, in case of power failure where auxiliary power cannot be maintained, no dangerous overcurrents results.

Previous load-dropping tests[1] where master-tripped cathode breakers were employed showed switching transient indexes as high as 8.25, roughly four times the highest transient observed on any of these tests. This contrast vividly illustrates the advantage to be gained by making power interruptions on large rectifier installations by tripping the line circuit breakers.

Results of Load-Pickup Tests

The procedure at Arkadelphia for restoring load following a power interruption is to close the line circuit breakers, unshort-circuit the ignitor circuits, remove firing delay, and then run the voltage regulator up to the normal position. This method was used in test 5, and the oscillogram made as the ignitor circuits were unblocked is shown in Fig. 4. No transients occurred in any of the rectifier units, load current building up uniformly in each rectifier.

Nomenclature

Electrical Characteristics of the Potline

Only limited data have been obtained on the electrical characteristics of fused electrolytic potlines used for reduction of metals. Circuit characteristics are important because the time required for load current to stop flowing after the start of a load-drop operation is affected quite appreciably by the inductance, resistance, and counter electromotive force of the cell line. These circuit constants depend upon the physical dimensions and layout of the cell room as well as upon the electrical properties of the metal, and it is not easy to determine them by direct measurement. Constants of the Arkadelphia line were obtained by relatively simple calculations based on the field test data. Similar data on other lines will have to be obtained if a clear picture is to be drawn of the range of constants for aluminum potlines in general.

A potline which is made up of a number of electrolytic cells may be represented by the equivalent circuit given in Fig. 5. Symbols are defined in the Nomenclature. The power supply, in this case 24 double-wye rectifier assemblies, is represented by the rectangular block. As long as any rectifier continues to pass current after the line circuit breakers open, the d-c busses are connected together by a circuit which includes the internal impedance of the rectifiers and transformers and the impedance of the d-c loop which connects each rectifier assembly to the d-c bus. When the line circuit breakers are opened, the terminal voltage of the power supply falls to a value determined by the impedance of this circuit. Since the largest impedances in the circuit are the arc-drop

Table III. Characteristics of the Potline

resistance of the tanks and the leakage in-between the d-c windings of the transformer

$$E_d'=\frac{1}{2n}\left(R_a i+L_e\frac{di}{dt}\right)$$

approximately. If several assemblies continue to share load current, as they did on these tests, the parallel impedance of this circuit is very low and the d-c bus voltage E_d' drops practically to zero. When conduction stops, the bus voltage rises immediately to the polarization value, or back electromotive force, of the potline, as shown in Fig. 3.

Neglecting E_d' which is very close to zero, the solution of the circuit is given by

$$p=\frac{E_d-E_b}{R} \qquad (1)$$

and

$$i=\frac{E_d}{R}\epsilon^{-\frac{Rt}{L}}-\frac{E_b}{R} \qquad (2)$$

When $i=0$, i.e., when load current stops

$$\epsilon^{-\frac{Rt}{L}}=\frac{E_b}{E_d} \qquad (3)$$

Equations 1 and 3 can be solved for R and L since everything else in them can be measured from the test oscillograms. The numbers substituted in these equations and the resultant solutions are tabulated in Table III. For the Arkadelphia line: $R=0.0057$ ohm, $L=0.77$ millihenry, and $E_b=211$ volts.

Arc-Back Tests

An arc back results from the formation of a cathode spot on the anode of a rectifier tank which permits current to flow through the tank in the reverse direction. It provides simultaneous paths for short-circuit current from the secondary winding of the rectifier transformer and from the d-c bus. Consequently, arc-back currents are nearly always higher than those resulting from a 3-phase fault on the rectifier transformer. Knowledge of the magnitude of fault current is necessary for determining the interrupting duty on circuit breakers employed for arc-back protection.

Analytical calculation of arc-back current is a long and complicated procedure because several different modes of operation take place as other rectifier tanks on the faulted rectifier start and stop conduction.[2] For this reason, a study of arc-back phenomena was made on the analogue computer,[3] and empirical curves were developed which give the first crest of current in the anode and cathode circuits, providing the circuit constants are known. The first crest of fault current is of special interest because it occurs about the same time that high-speed circuit breakers start to limit the increase of arc-back current. It is a measure, therefore, of the maximum fault current which the equipment is subjected to, as well as the determinant of circuit-breaker interrupting duty.

The arc-back protection system at Arkadelphia consists of high-speed anode and high-speed cathode circuit breakers located as shown in Fig. 1. This is a little different from the conventional protection system employed on large rectifier installations in this country. Most large installations are protected by high-speed anode breakers, with current-limiting reactors on the a-c side of the rectifier transformer in those applications where the arc-back current can exceed the interrupting rating of available anode breakers

‡Fig. 6.

§Fig. 6 with d-c loop shortened.

or the fault current rating of transformers and other equipment. The conventional practice is to use semihigh-speed cathode breakers to isolate the rectifier assembly from the d-c bus. Use of high-speed circuit breakers in both the anode and cathode circuits is a departure from usual practice; at this plant, the magnitude of arc-back current permitted the combination to be used without reactors. Objectives of the tests were to compare fault currents obtained in the field with calculated values and to observe arc-back phenomena on a large rectifier installation.

TEST PROCEDURE

A short-circuiting switch was connected in parallel with the ignitron tanks phase 1 of rectifier *6A*, as shown in Fig. 6, and arc backs were initiated by closing the switch with the same cam used to operate the oscillograph. Oscillograms were made of all six anode currents on the test rectifier and cathode currents on the test rectifier *6A*, the adjacent rectifier *6B*, and the most remote rectifier *1A*. Potline current was also recorded, the current being measured by taking the voltage drop across a section of the d-c bus.

The arc-back protection system at the plant employs high-speed circuit breakers in both the anode and cathode circuits. These breakers work on a flux-shifting principle, and start to open whenever there is a rapid reversal of the flux set up by normal load current. Twelve tests were made in which arc backs were cleared by the plant protection system. Initial conditions of the potline, recorded from meters on the operator's control board just prior to each test, are tabulated in Table IV which also shows the circuit arrangement for each test.

In practice, most arc backs start at the end of a conduction period at the point of transition between the conducting and nonconducting intervals. Currents from arc backs which occur at transition are larger than those from arc backs which occur later in the cycle. Since complicated timing devices are required to hit exactly on a transition point every time in the field, the time at which the fault was applied was left to chance. This procedure is satisfactory because closing the short-circuiting switch anywhere in the conduction period is equivalent to starting the arc back at transition, as the voltage is not in the right direction to force reverse current to flow until the nonconducting period begins. The time, expressed in cycles of the fundamental 60-cycle-per-second frequency, between the transition point and the start of the arc back is given in Table IV.

Table V. Results of Arc-Back Test 11

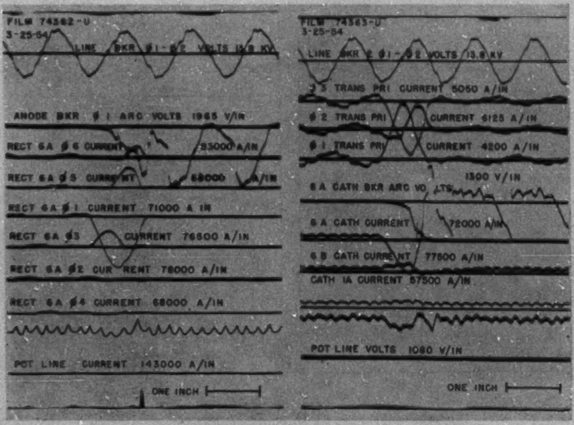

Fig. 7. Arc-back record, test 11

RESULTS OF ARC-BACK TESTS

In eight of the arc-back tests (tests 7, 9, 10, 11, 13, 14, 15, and 16), the fault was applied at, or very close to, the transition point. The oscillograms from test 11 are shown in Fig. 7, and values measured from them are tabulated in Table V. Oscillograms for the other arc-back tests are not included here because there were practically no differences in wave shapes or magnitudes between records on the eight transition shots.

The arc drop of the ignitron tanks under fault conditions limits the magnitude of arc-back current. In test 7, a 0.0018-ohm resistor was inserted in series with the short-circuiting switch to represent the equivalent arc-drop resistance of the faulted ignitron. The anode current in this test measured 62 kiloamperes, 3.1 per cent lower than in test 11 where the resistor was omitted. The reduction in magnitude appears about right, but it should be kept in mind that the observed reduction is comparable to the accuracy with which the oscillograms can be read. It was concluded that the resistor could be omitted as a conservative measure in subsequent tests without introducing significant error into the test results.

Another factor which influences the magnitude of fault current is the circuit consisting of the rectifier, its transformer, the interphase transformer, and the d-c loop (the feeders which connect the rectifier to the positive and negative d-c busses).

In tests 15 and 16, the area enclosed by the d-c loop was cut roughly in half by shortening the length of the connection from the interphase transformer to the negative d-c bus. Fault current magnitudes on these tests were practically the same as those tabulated in Table V, which substantiates the contention that most of the impedance to feedback current is presented by the inductance of the interphase transformer until it saturates.

Sympathetic arc backs are those which result from an arc back in another anode circuit. When they occur, the duration of the fault on the system is increased with corresponding increase in the disruptive effect of fault current stresses. The controlling factor in the production of sympathetic arc backs for any given ignitron design is the magnitude of forward-flow current fed into the original arc back by other ignitrons on the same wye group. In the tests, phase 5 carried crest currents of 24 kiloamperes divided between two parallel ignitron tanks. Not a single sympathetic arc back occurred on any of the 12 tests. Previous tests[4] have also shown that sympathetic arc backs are not likely to result from forward-flow currents of less than 13,000 amperes in ignitron tubes used in large electrochemical applications. The use of high-speed anode circuit breakers insures that forward-flow currents are kept at a minimum.

COMPARISON OF TEST AND CALCULATED VALUES

One objective of the tests was to compare magnitudes of arc-back currents obtained in the field with calculated values. The calculated values were obtained from empirical curves developed from an analogue computer study[3] and were based on the following circuit constants (see reference 3 for the curves and definitions of symbols):

$E_s = 750$ volts, line-to-neutral voltage on secondary of rectifier transformer
kva $= 4{,}750$, based on double-wye connection
$x_t = 7$ per cent, rectifier transformer reactance
$x_p = 1.5$ per cent, estimated reactance of regulating transformer plus high-voltage system
$L_d = 60$ microhenrys, inductance of d-c loop plus interphase transformer
$R_a = 0.0025$ ohm, equivalent arc drop of the ignitron during fault

Fault currents obtained from the curves are higher than those measured in the field for two reasons: the curves assume that the d-c bus voltage during the fault is 90 per cent of the prefault voltage, and limiting action of the circuit breakers is omitted in accordance with the standards for applying rectifier switchgear.

When an arc back occurs on a large rectifier installation there is a drop in d-c bus voltage caused by the voltage regulation of the parallel units feeding into the fault. The analogue computer curves[3] are based on the assumption that the bus voltage drops 10 per cent during an arc back. These tests show that a 27-per-cent drop in bus voltage is a more realistic figure at this installation. As the current in the cathode circuit is approximately proportional to the bus voltage, the value taken from the curves may be adjusted fairly accurately by multiplying by the factor (73/90). Since feedback current divides between the faulty anode and at least one normal anode on the same wye group,[3] the reduction of current in amperes through the faulty anode is about one-half the reduction in the cathode circuit.

Rectifier switchgear is applied on the basis of fault current which would be obtained if the circuit breakers were not present. In comparing field test magnitudes with calculated magnitudes of fault current, however, the limiting action of the circuit breakers used to clear the fault should be included in the calculations. In this case, the anode and cathode breakers were represented by resistances of 0.0050 ohm and 0.0025 ohm respectively. These values were obtained by taking the voltage across the breaker, corresponding to crest current, divided by the current. Such a representation assumes that the voltage developed by the circuit breaker is a linear function of the current, which is not strictly correct but close enough for comparison purposes.

Using the equivalent-resistance circuit-breaker representation with the circuit constants tabulated as in the foregoing, and following the procedure given in reference[3]

$$\frac{X_e}{R_e} = \frac{8.5}{2.6} = 3.3 \text{ and } \frac{X_s}{R_s} = \frac{8.8}{1.56} = 5.6$$

from which the following crest currents are obtained after adjusting the results from the curves for a 27-per-cent drop in bus voltage: anode circuit = 66,500 amperes; cathode circuit = 39,000 amperes. These check the measured values close enough for estimating purposes; see Table V.

KLYDONOGRAPH RECORDS

A great deal of study and exploratory testing has been devoted to the search for a source of transient overvoltages in rectifier installation.[1,4] Interest in this subject was generated by a few unexplained insulation failures at some earlier installations which appeared to have been caused by voltage stresses. However, no surge voltages have been indicated either on staged tests[1,4] or by the limited number of surge recorders which it has been possible to place in the field.[1] Nevertheless, the theory has persisted that transient overvoltages may be associated with switching operations, either for load dropping or clearance of faults. For this reason, during these tests, klydonographs were connected from each secondary terminal of the rectifier transformer to the neutral of the opposite wye, across the potline, and from phase to phase on the transformer secondary.

The highest voltage recorded in any location was 4,100 volts from the terminal of phase 5 to the neutral of the opposite wye group. Maximum voltages in the other locations ran from 2,000 to 3,000 volts. None of the voltages were high enough to damage the insulation provided on the rectifier transformer or other equipment. Similar results were obtained on previous tests.[1,4] With phenomena that are believed to occur seldom if at all, it is very difficult to draw definite conclusions from tests which give negative results. Nevertheless, the additional data from this investigation of transient overvoltages are reassuring.

Conclusions

Several conclusions may be drawn in the light of these field tests:

1. The best method for making voluntary load interruptions on large rectifier installations is by a-c line circuit-breaker operation with auxiliary power maintained on the rectifiers.
2. In case of power failure, high transient currents do not occur, but there is some shifting of currents between parallel rectifiers.
3. Where the a-c bus is sectionalized, the number of sections should be kept at the minimum consistent with equipment ratings.
4. No transient currents result from the procedure followed at this plant for picking up load.
5. The arc-back protection system consisting of high-speed circuit breakers in both the anode and cathode circuits showed excellent interrupting capability.
6. Calculated values of fault current obtained from analogue computer studies may be used with confidence.
7. With the ignitron design and protection system employed at this installation, the data indicate that sympathetic arc backs will not occur.
8. It is improbable that high surge voltages

are associated with circuit-breaker operations, either for load dropping or clearance of faults.

Discussion

C. A. Langlois (Reynolds Metals Company, Richmond, Va.): The authors are to be commended for an excellent paper. Very little factual information has been available on the inherent characteristics of an aluminum potline.

The subject of load interruption to rectifier supplied aluminum reduction plants has been a subject of discussion for many years. However, the method of load rejection by opening the incoming a-c oil circuit breakers has been a more common practice than might be indicated from the paper even though factual data of the desirability of this method was lacking.

In 1941 the Reynolds Metals Company built a reduction plant at Longview, Wash., consisting of three 32,000-ampere lines. The manufacturer's original instructions for load interruption were to turn off the master excitation or to open the cathode breakers with the master trip circuit. The use of the master excitation method was ruled out for fear of damage to the equipment because of the extreme currents carried by the last tanks firing. The master cathode trip method was not always the cleanest interruption, for many times arc backs would result. There have been cases where units on other potlines which were not being interrupted have had arc backs simultaneously with the interruption.

Since in most cases the load was finally dropped by the opening of an a-c circuit breaker, a program of making required interruptions by various methods and observing the results was initiated. Following these tests instructions were issued in August 1942 that planned interruptions of the load were to be made by use of the incoming feeder oil circuit breaker with auxiliary power maintained. This presented some problems, and switching had to be done since both the rectifier auxiliaries and the plant distribution system are supplied through this breaker. In spite of this the interruption was to be made by opening the oil breaker, turning off the master excitation and then closing the oil breaker to restore plant power. The use of the cathode trips was still to be used for emergency tripping. In 1948 one of the cathode breakers flashed over into the control circuits and a complete outage of the plant resulted. Since that time the only method of potline interruption has been by the use of the oil circuit breaker. In 1951 additions to this station were undertaken to increase the load from 32,000 to 52,000 amperes per circuit. At this time the auxiliary power supply and normal mill power supply were removed from the potline incoming a-c breakers and master cathode tripping eliminated.

In 1946 the Reynolds Metals Company took over the operation of the Plancor plant at Troutdale, Ore. This plant has four 55,000-ampere potlines and differs from the Longview plant in the manner in which the general lighting and power load is supplied. In this case the mill load is supplied through a separate oil circuit breaker. However the auxiliary power to the rectifier station is supplied through the oil circuit breakers supplying the rectifier power. The master excitation method of load interruption was never used; however, the use of master cathode tripping is the accepted method for emergency tripping. All emergency load rejection, such as frequency relaying or potroom emergencies, trip the cathode breakers. This has never caused any material damage nor have arc backs been a difficulty. However, if time will permit, the load is to be rejected by first transferring the auxiliary power to another feeder and then opening the incoming oil circuit breaker. This method has been in use at the Troutdale plant since 1948.

Late in 1951, plans were made to construct the plant in Arkansas where the load-dropping tests of this article were made. Initially it was planned to provide for both a-c tripping and d-c tripping with preference to be determined during operation. Early in planning, on the recommendation of the manufacturer, the provision for d-c tripping was omitted.

No operating experience to date on lines being tripped from the a-c side indicates that this method is in any way less desirable than d-c tripping and, in addition to the advantages stated in the field test report, the gain in operating simplicity is quite important.

Lysle W. Morton (General Electric Company, Schenectady, N. Y.): It is gratifying to those who have strong interests in mercury-arc power rectifier equipment to take note of the rating of this rectifier installation of 100 megawatts. From the paper it is obvious that this large installation of mercury-arc rectifiers in the United States is a successful job. The mercury-arc rectifier deserves increased respect as a versatile and reliable type of a-c to d-c conversion apparatus. Much credit should go to the engineers of Reynolds Metals Company and Westinghouse for their over-all accomplishment in carrying out such a large power rectifier project.

The load switching tests and arc back tests reported in this paper proved to be informative and have increased the application know-how of those who apply large groups of mercury-arc rectifiers. The authors and their colleagues deserve hearty congratulations for what they have done.

In general, the conclusions drawn from the results of these field tests appear to be warranted. The shifting of current between parallel rectifiers in test 4, when the auxiliary power was dropped simultaneously with main a-c power, may give rise to questions as to the transient distribution of currents among the various anodes of a rectifier section and as to what may have occurred in the 12 rectifier circuits not being measured. This is no criticism of the test procedure. The problems of recording all phenomena in all circuits of such a complex circuit are well appreciated. We can't help wondering whether the observations and data taken during that one test are dependable indications of what will occur in every case of unplanned loss of a-c power.

The use of high-speed cathode breakers in combination with high-speed anode breakers was effective in controlling the crest arc back current and keeping it within standard limits of 75,000 amperes. This is one way to accomplish that objective, but other methods involving current-limiting reactance may prove as effective and less expensive.

In respect to the voltage surge question, we should like to know whether the rectifier transformers or rectifier circuits were equipped with surge suppression, and if so, with what type.

W. Fraser (Aluminum Laboratories, Ltd., Arvida, Que., Canada): This paper gives a very complete picture of conditions which take place during a drop or pick-up of load on large rectifier installations.

It appears, however, that the value given in Table III for potline inductance is far too low, and the error results from using the open-circuit voltage of the potline for the value of E_b. The value of E_b/E_d for a cell operating as its normal voltage is around 0.34 but this value for a series of cells varies with the number of cells which are on so-called anode effect. A potline with a number of cells on anode effect will reduce the E_b value of the line and increase the value of R.

When tests are carried out to determine the inductance of an aluminum potline, it is absolutely essential that all cells are in normal operating condition. The number of cells in this particular potline is not mentioned by the authors, but the value of E_b can be obtained fairly closely from tests 1 and 2 by extrapolation. Using this value for all four tests gives the following results in millihenrys (mh):

Test 1, $L=0.841$ mh
Test 2, $L=0.848$ mh
Test 3, $L=0.914$ mh
Test 4, $L=0.903$ mh

The average value of L would therefore be close to 0.88 mh. If 15 per cent of the cells were on anode effect during the higher voltage conditions, the recalculated values of L for tests 3 and 4 would be 0.885 and 0.844 mh respectively, the average value for the line being 0.855 mh. The values shown in Table III for current and voltage during tests 3 and 4 indicate abnormal conditions in the potline.

J. K. Dillard, John Kiefer, and C. S. Hague: Several interesting points have been brought out. The cases mentioned by Mr. Langlois are particularly enlightening because actual field experiences are cited relative to load rejection by several different methods: 1. removal of excitation; 2. master trip of cathode circuit breakers; and 3. a-c breaker operation. These experiences substantiate the conclusion given in this paper and in an earlier paper (reference 1 of the paper) that the preferred method of dropping load is by a-c circuit-breaker operation with excitation maintained. The a-c breaker referred to by Mr. Langlois and in the paper, pertains to the circuit breaker back of the common high-voltage bus which feeds several parallel rectifiers. This point is worth reemphasis at this time, because in some countries the practice is to use an individual a-c breaker on each rectifier unit. Where this is the case, the cell line inductance forces high currents to shift to the last rectifier unit to determine whether the operation is made by master tripping the unit a-c breakers, or by master tripping the cathode breakers.

When this test program was being planned, as Mr. Morton suggests, considerable thought was given to just what phenomena would be recorded in order to make the best use of the oscillograph elements available. Anode currents were omitted on the grounds that these had been recorded on similar tests conducted 2 years previously (reference 1 of the paper). The 12 cathode *B*-unit currents which were not measured were scattered uniformly along the line. Since results of the test at Arkadelphia as well as those at Mead (reference 1 of the paper), did not show any unexplained phenomena taking place in either the anode or cathode circuits, the results from test 4 are probably as dependable as can be obtained from a very limited number of tests. In answer to Mr. Morton's specific question, no surge suppression devices are employed on either the transformers or rectifier circuits at Arkadelphia.

Mr. Fraser's comments about the operation of aluminum lines on anode effect present a good understanding of some of the phenomena observed on tests on these large installations. However, none of the pots at Arkadelphia were on anode effect during any of the tests, all of the cells being in normal operating condition.

The value of E_b cannot be obtained by substituting the values given for ρ and E_4 for tests 1 and 2 from Table III in equation 1, and then solving the resulting equations simultaneously. This procedure requires the difference taken of two large numbers and, even though each may be accurate to a very few per cent, there may be very large errors in the difference. The back electromotive force of the Arkadelphia line is lower than that usually encountered. When the tests were made, there were 160 pots in service, the E_b of these particular pots being about 1.3 volts, more or less. Dividing 208 by the d-c bus voltage, 842 volts, gives $E_b/E_4=0.248$ which checks the value measured from the oscillograms and shown in Table V. It therefore appears that the value of R and L given in Table V are also fairly accurate and that the values of inductance suggested by Mr. Fraser are too high.

Values in Table III for current and voltage during test 3 and 4 were not taken from recording meters but were read from instruments located on the operator's board. The inaccuracy in reading these instruments accounts for the slight discrepancy between these two tests in the table. The potline was in normal operating condition during both tests.

A Communications System for the New York State Thruway

D. S. DEWIRE
ASSOCIATE MEMBER AIEE

H. A. EVANS
NONMEMBER AIEE

WITH present-day rapid transportation requirements for passengers and commodities, with increasing numbers of highway freight-carrying vehicles, and with vehicles for pleasure-driving within the economic reach of nearly everyone, the need for nonstop express superhighways has become most urgent. Many of these highways have been constructed and are in operation, and many more are in process of construction or in the planning stages.

One of the basic needs in operating such highways is instant communication between all operating forces to make the highway as safe as it is humanly possible, to expedite public vehicular movement, and, so that it may be self-sustaining, to facilitate collection of tolls and protection of the collectors. This, of course, involves communication between supervisory offices, collection booths, and all associated official vehicles on the highway.

Any discussion of the communications system provided for the New York State Thruway requires, first, a basic understanding of the administrative organization and operating procedures used and second, a description of the communications requirements and the technical means provided for meeting them. In the preparation of this discussion, therefore, close collaboration has been necessary between the Thruway Authority and the Upstate Area of the New York Telephone Company.

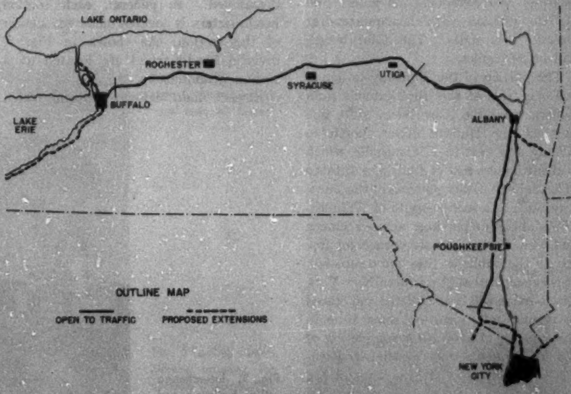

Fig. 1. Outline map of New York State Thruway

Paper 55-201, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing November 30, 1954.

D. S. Dewire is with the New York Telephone Company, Albany, N. Y., and H. A. Evans is with the New York State Thruway Authority, Albany, N. Y.

There have been many special problems encountered in designing this system. Meeting these problems and providing satisfactory communications for the Thruway has been accomplished through close understanding and co-operation between the New York State Thruway Authority, the New York State Police, and the New York Telephone Company, with invaluable assistance and advice from the American Telephone and Telegraph Company, the Bell Telephone Laboratories, and the Western Electric Company.

Description of the Thruway

The New York State Thruway is a superhighway operated on a toll basis. As shown in Fig. 1, it will eventually extend from the southern Westchester County line (northern New York City Line) to the Pennsylvania state line near Erie, Pa. Its route lies north from New York City to Albany, west to Buffalo and thence southwest toward Erie. Branches are planned to Niagara Falls, and to the Massachusetts, Connecticut, and New Jersey state lines to connect with superhighways in those states.

It is planned ultimately to establish four administrative divisions of the Thruway as follows: New York division with headquarters at Elmsford on the east bank of the Hudson River near Tarrytown, 95 miles in length; Albany division with headquarters at Albany, 150 miles; Syracuse division with headquarters near Syracuse, 154 miles; and Buffalo division with headquarters at Buffalo, 163 miles. The total length will be 562 miles.

The portion of the Thruway in actual toll operation at this time extends from Suffern, near the New Jersey state line west of the Hudson River, north to Albany and west to Williamsville, which is about 5 miles east of Buffalo, a distance of 393 miles. Other portions of the Thruway, such as a section south of Williamsville and certain portions between Suffern and New York City, are opened for free use by the public as they are completed. It is expected that the Suffern-New York City portion will be completed and placed in regular toll operation some time in the summer of 1955 after completion of a 3-mile bridge across the Hudson River just south of Nyack in the Tappan Zee section.

To facilitate administration pending completion of the entire project, the Suffern-Williamsville portion has been divided into two administrative divisions with headquarters at Albany and Syracuse. The Albany division is 169 miles long and the Syracuse division is 224 miles long. The division boundary falls in the vicinity of Fort Plain on the southern bank of the Mohawk River. When the Suffern-New York City portion is ready for toll operation, it is expected that the New York division will be established, with the boundary between the New York and Albany divisions falling in the vicinity of New Paltz, across the Hudson River from Poughkeepsie. Eventually, a Buffalo division will be established with a new division boundary near Rochester.

Each division is subdivided into maintenance sections from 25 to 35 miles in length. Each maintenance section has a section headquarters from which highway maintenance crews and vehicles are dispatched. In general, each section headquarters is located near the center of the section. As shown in Fig. 2, division headquarters are located at a section headquarters.

At each main highway crossing, which has been selected as a point of access to the Thruway, a traffic interchange has been established. This is so arranged that traffic entering or leaving the Thruway passes through a "trumpet" arrangement in which the toll collection booths are located. Each section headquarters and division headquarters is located at one of these interchanges. The Syracuse division at present has 7 section headquarters and 14 isolated interchanges, or a total of 21 interchanges. In the Albany division there are 6 section headquarters and 9 isolated interchanges, making 15 interchanges in all. This totals 2 division headquarters, 13 section headquarters and 23 isolated interchanges (or 36 interchanges) now in operation.

Operation of the Thruway

In the operation of the Thruway, many types of official vehicles are used. Of major importance are police vehicles which patrol the Thruway for traffic control, accident assistance, reporting of hazardous road conditions, and general promotion of safety along the Thruway. The policing operations are handled by a special detail from the New York State Police organization.

Secondary to policing functions are:

1. Highway maintenance, with various supervisors' cars and highway maintenance equipment vehicles such as trucks, scrapers, and snow plows.
2. Highway automotive service, consisting of panel trucks and tow trucks. These trucks are furnished by commercial garages off the Thruway with which the Thruway Authority has contracted for this service. Each garage operator is responsible for 24-hour patroling of an assigned portion of the Thruway.
3. Ambulance and fire service, at present called from off the Thruway when required.
4. Toll collections, with toll collectors' cars making the run over the Thruway periodically to collect from the various interchanges.

Fig. 3. Interchange utility building and toll booths

There are also various offices at the division and section headquarters and toll booths and a utility building at each interchange, which require fast and reliable communications service in the administration of the Thruway.

Communications Requirements

The communication requirements for the Thruway were outlined as follows:

1. Voice communication between authority headquarters and each division headquarters. At present, these voice communications requirements are met by the use of regular toll telephone service. It is anticipated that these requirements may grow to the point where it may prove economical for the Authority to arrange with the Telephone Company for the provision of a telephone channel for their exclusive use.
2. Teletype communication between Authority headquarters and division headquarters. At this time teletypewriter exchange or TWX service is in use. It is expected that this requirement may grow to the point where an exclusive-use teletypewriter channel may prove economical. This service is used primarily for administrative messages and for providing daily typed reports of collections in each division, but may be expanded to include weather reports, road conditions, and various other communications where a written record is desirable.
3. Telephone exchange service. Regular telephone service from the nearest telephone exchange is provided to all interchange toll booths and utility buildings, to

offices in section and division headquarters, and to restaurants and gas stations along the Thruway.

4. Public telephone service. Public telephone booths are provided at all restaurants and gas stations and may be provided at interchanges if it appears desirable.

5. Operations network. Instant communication is required between all Authority vehicles, toll booths, and operating offices in each division under the supervision of a dispatcher at division headquarters. In effect, this means one huge party line in each division by means of which any telephone, mobile or fixed, is able to communicate directly with any other telephone on the network by voice calling. Also, it appeared desirable to be able to operate individually that portion of the network covering any maintenance section, if the need should arise, with instant communication between all vehicles, toll booths, and section offices in that section. Of course, in times of emergency, this communications channel is extremely busy but, by the use of rigid discipline as to message content and priority of communications under the control of a capable dispatcher, messages are so regulated that a minimum of delay results. Occasional delays are tolerable in view of the operating efficiencies of a single-channel system.

Communications Facilities

Requirements 1 through 4 are provided by the usual forms of common carrier service, and the facilities employed need not be discussed in detail here. The balance of this discussion will, therefore, be devoted to item 5, the operations network.

To connect vehicles to this operations network, radio was, of course, the only medium which could be used. The network, therefore, became primarily a radio system. In designing this network, many basic problems had to be solved. These problems and their solutions are as follows:

THE FREQUENCY BAND IN WHICH THE RADIO PORTION OF THE NETWORK WOULD OPERATE

Since policing is a primary requirement, it appeared desirable for the Thruway Authority to request authorizations to operate in a police frequency band. All other operations fall in the emergency category, since highway maintenance and highway service are required for safety of the public, and toll collectors' booths and cars need instant contact with the police in case of attempted holdups. Frequencies were found to be available in the Police Radio Service in both the 40- and 160-megacycle bands. Since all radio communication requirements are limited to the Thruway or its immediate vicinity, the 160-megacycle band is desirable to permit the use of economically feasible directional antennas where necessary. Further, this band is not as sus-

Fig. 11. Division bridge equipment

Fig. 12 (left). Dispatcher's control console

Fig. 13 (right). Isolated interchange bridge equipment

ceptible to skip and noise interference as the 40-megacycle band.

MAIN RADIO STATION LOCATIONS

For both operating and maintenance reasons, it was decided to locate main radio stations along the Thruway right-of-way. The distances separating proposed locations of section headquarters closely approximate calculated reliable coverage distances obtainable with reasonable radio transmitter powers and antenna support heights at these locations. The radio equipment is located in Thruway buildings, where heated quarters and emergency power are available. Access to the radio equipment is controlled by the Thruway Authority which is, of course, the licensee for the system. Since each section headquarters is located at an interchange, the Telephone Company maintenance people have access to the equipment location either from the connecting highway or from the Thruway.

It was necessary that these main radio stations be arranged as mobile relay stations (a 2-frequency system) so that communications between mobile units would be possible over an entire division. It was also necessary that they operate as base radio stations since they are controlled remotely from division headquarters and are directly connected to local telephones on the network in toll booths and section headquarters offices.

INTERCONNECTION OF MAIN RADIO STATIONS

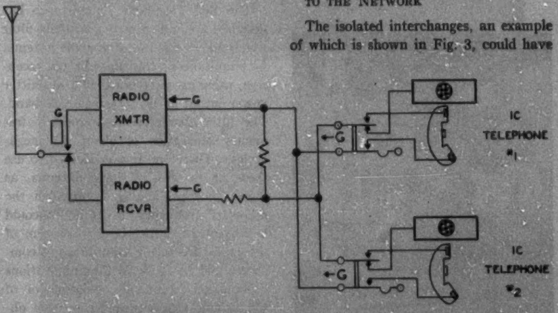
To provide one common network for an entire Thruway division, it is necessary that all main radio stations be interconnected for simultaneous operation. Although there were some advantages to be obtained by connecting these stations by microwave, studies indicated this to be neither as economical nor as dependable as the use of channels in existing main route or back-bone cables which closely parallel the Thruway. To be economical, microwave required a minimum of five channels in all parts of the system. Need could be foreseen for only three channels in some places. Further, the failure of one microwave station in the interconnection path would disrupt network communications until it could be placed back in service.

On the other hand, failure of any one back-bone cable is not serious since there are several cables along this route, paralleled by a main route microwave system. Further, in the unlikely event of failure of all back-bone routes, connection can be established readily from division headquarters to one or more section headquarters around the alternate main route between New York and the West via Pittsburgh and Cleveland.

In interconnecting the main radio stations, it is necessary to provide for individual operation of any section in an emergency without disturbing the rest of the division network. This was solved by carrying a channel from each main radio station back to a central point, at division headquarters. This permits provisions of an automatic selection circuit at division headquarters so that an incoming call via any section headquarters can lock out incoming calls from any other section headquarters. With microwave, this would have required as many as five channels in some sections, which means that a microwave equipment failure might isolate five sections at one time.

CONNECTION OF ISOLATED INTERCHANGES TO THE NETWORK

The isolated interchanges, an example of which is shown in Fig. 3, could have



NOTE: PUSH-TO-TALK ORIGINATING AT "G" ACTUATES EQUIPMENT AT "G".

Fig. 14. Block diagram of isolated interchange bridge equipment

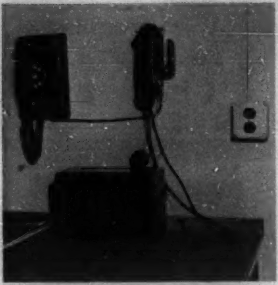


Fig. 15. Interchange utility building telephone equipment

been connected to the network by wire lines. This would have required the placing of many miles of new wire line facilities. It appeared economically desirable to locate a low-power base radio station at each such interchange to operate into the network in the same manner as mobile stations. This has proved a most satisfactory solution.

Connection of Section Headquarters Telephones to the Network

Since the toll booths, utility building, and section offices local to each section headquarters are to be in buildings reasonably close together, it is relatively simple to interconnect all network telephones in these buildings by cable with a specially designed bridge equipment, as shown in Fig. 4. The main radio station at that point is made a part of the bridge.

Connection of Division Headquarters Telephones to the Network

This is accomplished in the same manner as the section headquarters, with the addition of a control console for the division network dispatcher.

Fig. 16. Interchange booth

Radio System Transmission Design

In establishing main radio stations, theoretical computations were made based on studies of topographical maps. These computations were tempered by the wide experience of the Telephone Company engineers in mobile radio performance throughout the general area of the Thruway. In questionable cases, field tests were made to determine the validity of the computation-experience results and modifications were made in accordance therewith. The results of the computations and tests determined the required antenna height at each main radio station location, the radiated power which would be required, and the type of antenna to be used. Antenna heights vary from 75 to 135 feet above ground level at the radio station sites.

Communication between vehicles required use of a 2-frequency system with each main radio station designed to receive simultaneously a call on one frequency and retransmit it on another. There were several ways in which this could be done. Two antennas horizontally spaced by at least 200 feet would have been satisfactory. This would have meant two antenna supports from 60 to 120 feet in height. The supports had to be free-standing, since the design of roadways and buildings at each section headquarters precluded the use of guys. Two structures were undesirable both from space and economic standpoints. A single antenna support with antennas vertically spaced by at least 20 feet would have been possible, but this would have increased the height of the supports from 80 to 140 feet, which was also undesirable from an economic standpoint.

The Bell Telephone Laboratories has designed a small, compact antenna filter which allows the use of a single antenna for simultaneous transmission and reception, using up to 60 watts of transmitter power output in the 160-megacycle band. The filter characteristics require a frequency separation of about 4.5 megacycles. Therefore, it was decided to use these filters with a single antenna, as shown in Figs. 5 and 6, provided the necessary frequency assignments could be obtained. With the co-operation of the police frequency co-ordinating committee and the Federal Communications Commission, frequency assignments of 154.65 and 159.15 megacycles were obtained by the Thruway Authority.

Because of the power-handling capabilities of the new filters and previous experience, it was desirable to limit the power output from any main radio station transmitter to 60 watts. With the antenna heights mentioned in the foregoing and the use of gain antennas, this has been generally adequate. However, at each of two locations, subsequent operating experience has dictated the use of a 250-watt transmitter, with one cavity filter having greater power-handling capabilities.

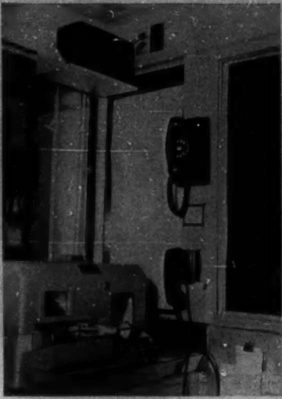

Fig. 17. Interchange booth telephone equipment

It was originally planned to direct antenna radiations along the Thruway. This would have required the use of two directional antennas, with maximum radiation in opposite directions, at each main radio station. An equivalent or better gain in antenna radiation could be obtained by the use of a single omnidirectional gain antenna, although radiations would then not be confined to the Thruway. The latter has proved generally desirable, since it is necessary to reach State Police barracks off the Thruway where the police who patrol the Thruway are quartered. If in the future

Fig. 18. Police car

Fig. 19. Police car radio equipment

Fig. 20. Police car radio control equipment

it becomes necessary, because of possible interference with other police systems, to direct radiations along the Thruway, the omnidirectional antennas can be replaced with directional arrays.

There are two or three cases where a section headquarters is near one end of a section. Here a single corner reflector is used rather than a gain antenna to cover that section. There is at least one case where two corner reflectors are used rather than a gain antenna to minimize the possibility of interference from other police systems using the same frequencies.

Calculations indicated that a low-power radio station would be sufficient at any isolated interchange. At isolated interchanges within a few miles of a base and mobile relay station, a whip-type antenna on the radio cabinet, as shown in Fig. 7, has proved adequate. For isolated interchanges at a greater distance, a corner reflector antenna is used mounted on a chimney bracket on the utility building, as shown in Fig. 8, directed toward the nearest base and mobile relay station. This makes it possible to use the low-powered radio equipment and also prevents hash in incoming messages where the signal strength from two adjacent base and mobile relay stations might be nearly equal. These isolated interchange radio stations have been classed by the Federal Communications Commission as base stations while the main radio stations are classed as base and mobile relay stations.

The radio transmission objective was 100-per-cent satisfactory coverage along the route of the Thruway. With the transmitter powers, tower heights, and antennas provided this objective has been realized. Hash areas exist where transmissions to a mobile unit are distorted because of phase differences from two adjacent transmitters in equal signal strength areas. However, with the system design employed, these areas are very short and, in general, have little effect on intelligibility. Occasional cases of more severe distortion present no particular problem, since on a report of unintelligibility the dispatcher can disable one of the two transmitters and repeat the message over the other. Because of the selective features of the division bridge, hash on calls incoming from mobile units or isolated interchanges does not exist, since the selected receiver locks out all others.

BRIDGE EQUIPMENT DESIGN

It was mentioned that the telephones and radio equipment at each section headquarters are interconnected by means of a bridge. The requirements to be met by this bridge equipment were:

1. Reradiation, on the main radio station transmitter frequency, of incoming calls from mobile units or isolated interchanges.
2. Reception of all calls at all telephones on the division network.
3. Voice calling.
4. Prevention of interruption to transmissions in progress.
5. Assignment of a control station, in accordance with the Federal Communications Commission rules, which would have a "carrier on" indication to show when the radio transmitter control circuits were energized, and a radio transmitter cutoff key to disable the radio transmitter in case of trouble which would produce unauthorized radiations.
6. A radio receiver cutoff key, readily available in case of trouble in the receiver of presence of an external noise condition

Fig. 21. Thruway passenger car radio equipment

Fig. 22. Dump truck

Fig. 24. Dump truck radio control equipment

which might lock the receiver in and cause noise over the entire network.

7. A push-to-talk handset and a loudspeaker with individual amplifier at each telephone.

8. At local interchange telephones, the ability to talk and receive on the network and also the ability to intercommunicate between themselves without affecting the network.

9. At all other telephones the ability to communicate on the network only.

The bridge equipment at each section headquarters is illustrated in Fig. 9. The heart of this bridge circuit is, as shown in Fig. 4, an amplifier which accommodates an outgoing circuit to the radio transmitter, an incoming circuit from the radio receiver, a 4-wire line circuit on which all interchange telephones are bridged, a 4-wire line circuit on which all other telephones are bridged, and a 2-wire line circuit to the division bridge. The amplifier is provided with an input bus and an output bus both designed for low impedance to minimize effects of trouble on any connected circuit. To provide the push-to-talk control feature, each radio receiver is equipped with a carrier-operated relay, and a control relay was provided in each telephone circuit. Push-to-talk control is also transmitted by means of control relays and a telegraph channel from the section bridge to the bridge at division headquarters. On a transmission in progress, all push-to-talk control is locked out except from the originating telephone and the dispatcher.

The bridge equipment at division headquarters is illustrated in Figs. 10 and 11. This bridge has the same requirements as the bridge at each section headquarters with certain additions and exceptions. In addition to the other telephones at section headquarters, there are other telephones in the division offices, and a network dispatcher. The dispatcher is required to have certain controls for the entire network. He can interrupt and take over the network from any other fixed or mobile telephone in case of emergency by merely depressing his push-to-talk button. He can disable the local transmitter and the local receiver. He has a "carrier on" indication for his local radio transmitter and also for all other main radio transmitters in the network as long as they are operating on a complete network basis. He can disable the radio transmitter at each remote main radio station as long as this station is operating on a network basis. He can cut off each line to a remote main radio station so that, in case of line trouble, the station affected can operate independently from its local control telephone. The dispatcher operates from a microphone. All other telephones, including those in mobile units, are equipped with handsets.

Fig. 23. Dump truck radio equipment

As with the section bridge, the heart of the division bridge is a main amplifier. Circuits are terminated on this amplifier in a manner similar to those at a section bridge, with the addition of a line circuit for the dispatcher and line circuits for all remote section bridges. A small console, shown in Fig. 12, is provided for the dispatcher, to accommodate a loudspeaker and amplifier, microphone preamplifier, control keys and associated guard lamps, and the "carrier on" lamp.

A small, relatively simple bridge is provided at each isolated interchange, as shown in Figs. 13 and 14. The requirements at this bridge differ considerably from those at the section and division bridges. Neither reradiation nor prevention of interruption, or lockout, are required. It has been necessary to assign a particular telephone as a control station, and to provide at this telephone a "carrier on" lamp and transmitter cutoff key. A receiver cutoff key is located in the utility building. All telephones require access to the network and also intercommunication without disturbing the network. Since each loudspeaker at a telephone has its own individual amplifier intercommunication is possible without

Vol. 7
Pt. 1
1955

additional amplification. Interchange telephone equipment is illustrated in Figs. 15, 16, and 17.

Control features at the various bridges are of interest. At a section bridge, the local radio receiver is equipped with a carrier-operated or codan relay, which operates whenever an incoming call is received from a mobile unit or nearby isolated interchange and provides a push-to-talk control signal. This signal disables the push-to-talk control from all local wire-connected telephones, activates the associated radio transmitter, and places a control signal over the control channel from the section bridge to the division bridge. At the division bridge, this control signal disables the push-to-talk control from all wire-connected telephones except the dispatcher, disables the codan control from the division radio receiver, activates the division radio transmitter, and is transmitted out over the control channels to all other section bridges. At the other section bridges, receipt of this control signal disables the push-to-talk control from all local wire-connected telephones, activates the section radio transmitter and disables the control from the section radio receiver. Disabling of all push-to-talk controls except that of the originating telephone prevents interruption by any other party except the dispatcher. Likewise, with a clear channel, depressing the push-to-talk button at any wire-connected telephone at a section bridge disables all other controls, activates the local radio transmitter, and passes the control signal to the division bridge and all other section bridges.

Operation at the division bridge is similar except that the dispatcher's control is never disabled. The dispatcher may, at any time, by depressing his push-to-talk button, disable all other controls and activate all main radio transmitters. This is accomplished by use of a single control channel between each section bridge and the division bridge which is a reversible channel to transmit control in either direction. In addition, this same control channel, by the use of polarized relays and reversed battery, is used for remote transmitter cutoff under control of the dispatcher.

Mobile Units

The mobile units used in this system, illustrated in Figs. 18 through 24, transmit on the main radio station receiver frequency and receive on the main transmitter frequency. The transmitters are of 25-watt power output, which has proved adequate. The noise conditions at the cars are somewhat more severe than those at the main radio station, so that 25 watts at the cars and 60 or 250 watts at the main stations provide a well-balanced system. Mounting arrangements in the cars were somewhat of a problem but have been worked out satisfactorily for the various types of vehicles used. The police cars, illustrated in Fig. 18, had a special problem since it was required that these cars have radio units on both the Thruway channel and the State Police channel. The State Police channel utilizes frequencies in the 40-megacycle band. Therefore, it was necessary to install two complete units. The transmitter and receiver chassis are placed on the shelf in the luggage compartment, as shown in Fig. 19. Both control units are located under the dash in the front, Fig. 20, with both loudspeakers under the grilled opening in the dash. The 40-megacycle antenna is mounted on the left rear fender, and the 160-megacycle antenna in the middle of the roof, as shown in Fig. 18.

Special Feature

One interesting special requirement concerned emergency intercommunication between the Thruway dispatcher and State Police Troop Headquarters along the Thruway. A monitoring receiver on the State Police channel is installed adjacent to the dispatcher's console, as shown in Fig. 12. Because of the nature of the wire network connecting the radio stations of the State Police system, a Troop Headquarters can activate the State Police radio station nearest the Thruway division headquarters and be heard on the monitoring receiver. Likewise, a monitoring receiver on the Thruway channel is installed in the Troop Headquarters, and all communications over the Thruway channel are heard on it.

Several other special features have been found desirable by the Thruway Authority since this system has been placed in operation. Provision of these features has presented new design problems which are being worked out for application to the system. When complete, it is expected that the Authority will have one of the most comprehensive and efficient communications systems ever provided.

Coaxial Cavity Filters for Multiplexing of 900-Megacycle Radio Relay Systems

M. H. KEBBY
ASSOCIATE MEMBER AIEE

Synopsis: Band-pass filters have been developed to provide for simultaneous application to a single antenna of two or more radio transmitters and/or receivers operating in the 900-megacycle (mc) range. By multiplexing transmitters or multiplexing receivers, or by diplexing a transmitter and receiver, considerable saving can be realized in equipment cost for multichannel radio systems. Filters consist of one or more sections of coaxial transmission line in tandem, adjusted for the desired degree of selectivity. In addition, filters are used to provide preselection and harmonic suppression where separate antennas are used for each transmitter and receiver.

ANTENNAS used with microwave radio systems are normally capable of handling efficiently a much wider band of frequencies than is required for a single, unidirectional group of communication channels. In this respect, antennas can be compared to open-wire lines or cable pairs, both of which are capable of transmitting a wider frequency band than is occupied by a single telephone channel or group of channels in a particular part of the frequency spectrum. Just as physical lines are commonly multiplexed to use fully their transmission band capabilities, so are microwave antennas used for simultaneous transmission and/or reception of more than one group of radio channels. Physical lines are multiplexed by using coil-capacitor or, in some cases, crystal filters to separate the various frequency bands involved. Although such conventional filters are not practical at micro-

Fig. 1. Frequency allocation for operation of three type-72B-900 radio systems over one path

Frequencies shown with transmitter and receiver assemblies in mc

wave frequencies, other types of frequency selective devices can be used.

In the 900-mc region, coaxial cavities are the most practical and economical type of filters, largely because of their excellent electrical characteristics and convenient size. Such accessory equipment is used in the recently developed Lenkurt type-*72B* radio systems. Although designs available at present use short-circuited quarter-wave coaxial sections tuned for operation only in the 900-mc band, similar filters are practical for other frequency ranges.

In possible applications of type-*72B* radio equipment, it is anticipated that up to three parallel radio circuits may be required in the 900-mc band (890 to 936 mc), and a frequency allocation permitting such operation has been established, as shown in Fig. 1. After allowances for such factors as cross-coupling, overshoot, and spurious responses, filters have been designed with sufficient selectivity to permit a minimum separation of 12 mc between any transmitter and receiver operating on the same antenna. Minimum separation between two transmitters or between two receivers on a single antenna is 6.3 mc.

Fig. 2. Approximate equivalent circuit of coaxial cavity filter near resonance

Coaxial cavity filters acting as multiplexers, diplexers and multidiplexers have been developed for the following equipment combinations.

1. One transmitter and one receiver: diplexer.
2. Two transmitters:
3. Two receivers:
4. Three transmitters:
5. Three receivers:

} multiplexers

6. Two transmitters and two receivers: multidiplexer.

Coaxial Cavities as Radio-Frequency Filters

Coaxial cavity filters consist of one or more short segments of coaxial transmission line with each segment corresponding to an individual mesh of a conventional coil-capacitor filter. Each line section is effectively a quarter wave long at the center of the passband (referred to as the resonant frequency); it is short-circuited at one end and open-circuited at the other, with coupling loops provided for the input and output connections. In the vicinity of resonance, the impedance-frequency characteristics of such a line are equivalent to those of a lumped-constant parallel-resonant circuit with an equivalent Q. Generally, the desired attenuation characteristics of the radio-frequency filter lie in the frequency range of about 5 per cent above and below the resonant frequency. Therefore, within this range, standard response curves relating bandwidth and Q derived for lumped-constant circuits may be used.

The frequency of resonance of a transmission line in mc is given approximately by $f=246n/L$, where n is the number of quarter-wave lengths along the line and L is the line length in feet. In a radio-frequency filter, a line is ordinarily used at its lowest possible (fundamental) resonant frequency, in order to have the greatest possible frequency separation between higher-order resonant modes. With a short-circuited quarter-wave line, the closest resonant frequencies occur at odd multiples (3, 5, 7, etc.) of the fundamental frequency, while with a half-wave open line the higher-order modes

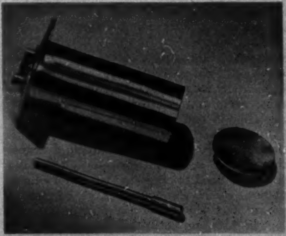

Fig. 3. 900-mc coaxial cavity filter

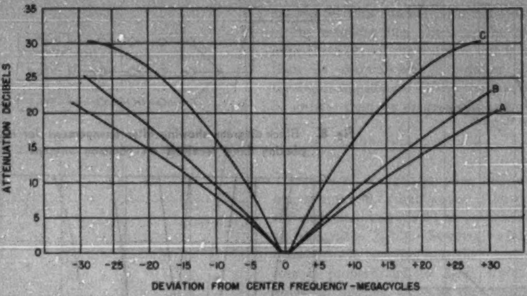

Fig. 4. Attenuation versus frequency characteristics of single-section coaxial cavity filter for several coupling conditions

are even multiples of the fundamental. In addition, the quarter-wave line is shorter and occupies less space, an important consideration in the ultrahigh frequency and lower microwave spectrum. For these reasons, a quarter-wave line was selected for this design.

Coupling Methods

Various arrangements can be used for coupling energy into and out of tuned cavities. The coupling may be either magnetic or electric. Coupling to the magnetic field is most effective near the short-circuited end of a quarter-wave line where the current density is greatest, while coupling to the electric field is most effective near the open-circuited end where the highest voltage gradient exists. Magnetic coupling may be obtained by placing a small loop of wire or ribbon (which is connected to a coaxial transmission line) in the cavity. Electric coupling is usually accomplished with a small capacitive probe, formed by extending the center conductor of the coaxial transmission line into the cavity.

Magnetic loop coupling has been chosen as the most practical method in the present design. The loops protrude through the short-circuiting plate of the coaxial cavity. Input and output loops are placed on opposite sides of the center conductor to provide minimum direct magnetic coupling between the loops. Such coupling between loops would tend to reduce the selectivity of the filter.

The effect of coupling loop position may be seen by considering an approximate equivalent circuit of a cavity filter near resonance (Fig. 2). The loop inductances (L_1 and L_2) will be tuned out by the resonant circuit (L_0 and C_0); however, they should be kept as small as possible to prevent altering of the impedance characteristics of the resonant circuit.

The mutual coupling (M_1 and M_2) between the loops and the resonant circuit is dependent upon the loop areas and their position and orientation in the magnetic field. The input impedance at resonance is dependent primarily upon the relationship between M_1 and M_2 (for a given load impedance). Generally, M_1 is made equal to M_2, so that at resonance, the input impedance is approximately equal to the load impedance. At other frequencies, the input impedance is dependent more upon the impedance of L_0 and C_0 which, of course, drops as the frequency deviates from resonance. This in turn results in an extremely low input impedance which is practically independent of the load impedance.

The rate at which the input impedance drops as the frequency deviates from resonance (selectivity of the filter) is dependent upon the loaded Q of the resonant circuit; this is determined primarily by the value of M_2 (for a fixed load impedance). Thus, the selectivity of the filter may be changed by altering the coupling, a relatively simple matter with rotatable coupling loops.

Insertion Loss

Filter losses at resonance are primarily caused by dissipation and mismatch. Dissipation within the filter may be kept to a minimum by using a high-conductivity material on the inside surfaces of the cavity. A good, low-impedance short circuit at the short-circuited end of the line is also important. As in a lumped-element circuit, dissipation results in a finite unloaded Q. The magnitude of the dissipation loss generally lies between 0.25 and 2 decibels (db) and is given by[1]

$$\text{dissipation loss, db} = 20 \log \frac{Q_u}{Q_u - Q_l}$$

where Q_u = unloaded Q and Q_l = the loaded Q.

The magnitude of the mismatch loss is determined primarily by the relationship between input and output coupling factors (M_1 and M_2 in Fig. 2) and the load

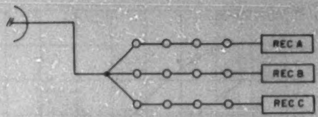

Fig. 8. Block diagram showing filter arrangement for multiplexing three receivers on common antenna

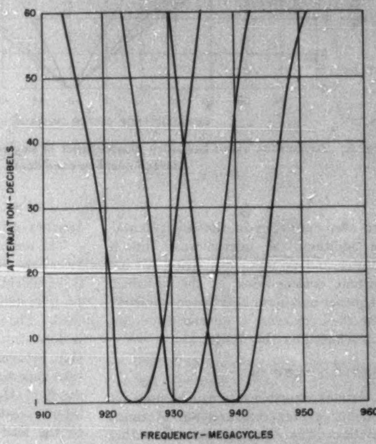

Fig. 9. Attenuation versus frequency characteristics of three flanking 4-section filters as used for receiver multiplexing

and source impedances. It is generally less than 0.1 db.

Practical Filters

A typical quarter-wave short-circuited coaxial cavity filter section is shown in Fig. 3. The cavity has an outside diameter of 2 inches, a length of approximately 6 inches over all, a characteristic impedance of approximately 80 ohms, and an unloaded *Q* of greater than 2,000. The length of the center conductor is adjustable to allow tuning from 890 to 960 mc.

Fig. 4 shows a set of measured curves giving the attenuation-versus-frequency characteristics of a single filter section. Curve *A* was taken with the coupling loops set in a position of maximum coupling; insertion loss at the center frequency was 0.25 db. Curve *C* was taken with the coupling loops set to allow very little coupling; insertion loss for this position was 1 db. Curve *B* was taken with the loops in an intermediate position. The maximum attenuation for the condition of the loops adjusted for maximum coupling is about 32 db, and is limited by the direct magnetic coupling between the input and output loops.

Multisection Filters

Several coaxial cavities are cascaded to provide more attenuation outside the passband than is possible with a single filter section. Selectivity to some extent is controlled by the degree of coupling; however, as the coupling is reduced, the passband may become intolerably narrow and/or the filter may become too critical to adjust. Under such conditions, it is necessary to add one or more sections to obtain adequate selectivity.

The most convenient method of coupling between filter sections is through transmission lines of an odd multiple of quarter waves in length.[9] This length is not critical, however, as shown in Fig. 5, where the attenuation characteristics are plotted for several lengths of coupling line.

Fig. 6 shows a set of curves measured with one, two, and four filter sections in tandem. Each section was adjusted to provide the same attenuation and insertion loss. The total insertion loss of the filter sections in tandem at resonance is the summation of the insertion loss of the individual filters; however, it is interesting to note that the attenuation for a given frequency outside the passband is greater than that of the sum of the attenuation of the individual filters. This is because of the increased mismatch loss created by the impedance-transforming properties of a quarter-wave length of transmission line. This can best be described by reference to Fig. 7. At a given frequency outside the passband, the input and output impedances of the filters

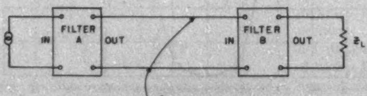

Fig. 7 (left). Block diagram of 2-section filter showing quarter-wave length coupling line

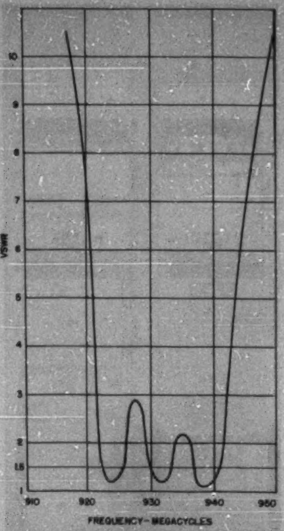

Fig. 10. Variation of VSWR with frequency on antenna transmission line. Three receivers multiplexed through 4-section cavity filters were used as load

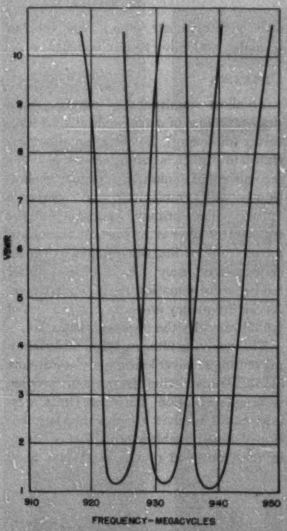

Fig. 11. Variation of VSWR with frequency on individual receiver lines using 4-section filters and antenna as load

are less than the characteristic impedance of the coupling line. Because the load impedance (Z_1) of the coupling line is less than its characteristic impedance (Z_0), the input impedance (Z_i) to the line will be greater than its characteristic impedance, i.e.

$$Z_i = Z_0^2/Z_1$$

With a zero-length coupling line (or a line a multiple of half-waves in length), the mismatch loss would be proportional to the ratio Z_0/Z_1; however, with a quarter-wave coupling line, the mismatch loss is proportional to Z_i/Z_1 which is equal to Z_0^2/Z_1^2. Loss at the passband frequencies is not affected, since the line is terminated in its characteristic impedance.

Applications

Coaxial cavity filters are used at present with Lenkurt type-*72B* radio systems for: 1. receiver pre-selection; 2. receiver multiplexing; 3. transmitter harmonic suppression; 4. transmitter multiplexing; 5. transmitter-receiver diplexing; and 6. multidiplexing.

Receiver Preselection

When the first stage of a superheterodyne receiver is a mixer, some form of filtering must be provided between the antenna and mixer to prevent extraneous signals from entering the mixer and causing interference. A 2-section filter having the attenuation characteristics shown in Fig. 6 is generally used on the type-*72B* receivers for preselection. In applications where extremely close spacing of transmit and receive frequencies is necessary, a 4-section filter may be used to provide the required additional selectivity.

Receiver Multiplexing

When used to multiplex more than one receiver on an antenna, the coaxial cavity filters must furnish sufficient isolation between receivers to prevent loading of the antenna at frequencies other than the operating frequency of the individual receivers. When coaxial cavity filters are used for multiplexing, they also act as receiver preselection filters, since the requirements for preselection are less severe than for multiplexing. In many cases, sufficient isolation could be provided by a 2-section filter between each receiver and the common line; however, because of the multiplicity of transmitters which usually exists at a location where receivers are multiplexed, the possibility exists of spurious frequencies' causing objectionable interference into the receiver. For this reason, the greater selectivity provided by 4-section filters is desirable.

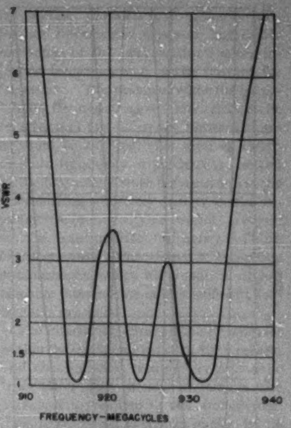

Fig. 12. Variation of VSWR with frequency on antenna transmission line. Three transmitters multiplexed through 2-section cavity filters were used as load

Fig. 8 shows a block diagram of the arrangement commonly used to multiplex more than one receiver on an antenna. The total insertion loss of each 4-section filter is 2 db. Attenuation-frequency characteristics are shown in Fig. 9. As previously explained, the filter input impedance is very low off resonance; therefore, to make the off-resonant input impedance very high (looking at the filters from the junction), the line interconnecting the filters and the junction block is made three-quarters of a wave length. At the resonant frequency, of course, the line input impedance at the junction is almost equal to the receiver input impedance.

Fig. 10 shows the variation of voltage standing wave ratio (VSWR) with frequency on the antenna transmission line with three receivers multiplexed on a common antenna. The maximum VSWR at resonance is 1.20, which results in a mismatch loss of less than 0.1 db. Fig. 11 shows the variation of VSWR with frequency on each of the receive lines between the filters and receivers, using the filters as a load and assuming a perfect match at the receiver.

Transmitter Harmonic Suppression

A single-section filter is generally used in the transmitter to provide the neces-

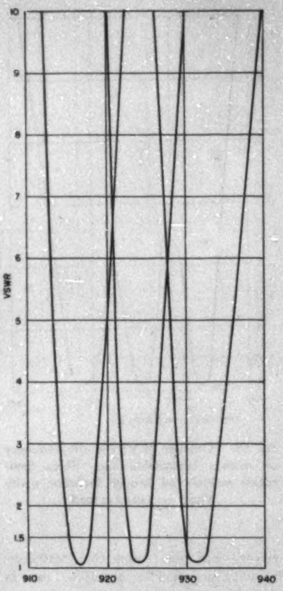

Fig. 13. Variation of VSWR with frequency on individual transmitter lines using 2-section filters and an antenna as load

sary suppression of harmonic radiation. A filter having attenuation characteristics as shown in curve *A* of Fig. 4, will generally ensure that harmonic radiation is at least 70 db below the unmodulated carrier.

TRANSMITTER MULTIPLEXING

Transmitter multiplexing filters must provide sufficient decoupling between transmitters to prevent the creation of intermodulation products of a disturbing nature in the final transmitter stage; in addition, they must allow loading of the antenna only at the operating frequency of each transmitter. Filters which provide the necessary attenuation for multiplexing automatically provide the required harmonic suppression, since the latter requirement is less severe.

It has been found that at least 25 db of isolation is required between type-*72B* transmitters to insure that spurious products will be more than 75 db below the transmitter unmodulated carrier. This requirement is particularly severe in the case where three parallel links are in operation with transmitters equally spaced in frequency. Under these conditions, the third order $(2F_c - F_h)$ or $(2F_c - F_l)$ product between the center- and high- (or center- and low-) frequency transmitters falls directly on the low- (or high-) frequency transmitter. This product, if it reaches the receiver with sufficient intensity, will result in an objectionable beat frequency which could cause interference in a carrier-derived voice channel.

A 2-section filter is adequate when the frequency separation between transmitters is at least 7.5 mc. However, where the separation is 6.3 mc, a 4-section filter must be used. Each filter section has an insertion loss of about 0.5 db and attenuation characteristics, as shown in Fig. 6.

Fig. 12 shows the VSWR variation with frequency of a 2-section filter on the common transmission line, using the filters as a load. Fig. 13 shows the VSWR characteristics of a 2-section filter on the individual transmitter lines, assuming a perfect match at the transmitter.

Figs. 10 and 11 show the VSWR characteristics for a 4-section filter. (Although the filters were discussed in connection with receiver multiplexing, the characteristics apply equally well for use with transmitters.)

Fig. 14 shows a photograph of two type-*72B* transmitters which will be multiplexed upon one common transmitting antenna. The multiplexer panel is shown near the top of the transmitter on the left-hand side; it has a capacity of three transmitters. Four-section filters are used in this case because the frequency separation between transmitters is only 6.3 mc. For this particular application, the traffic load is such that two circuits will provide the necessary capacity at this time; however, at the present rate of growth, it is estimated that within a few years one additional circuit will be required. The frequency for this additional circuit has been allocated and the multiplexer filters tuned and factory-tested. At the time of installation of the third transmitter, a cable patched between the multiplexer and transmitter power output panel will be the only requirement for connection of the new transmitter to the existing antenna system. Although not shown in the photograph, a similar arrangement is provided for the receiving system. This *72B* radio circuit has an ultimate capacity of 216 toll-quality telephone channels and 3 v-f order wire channels, plus a large number of alarm and pilot tone channels.

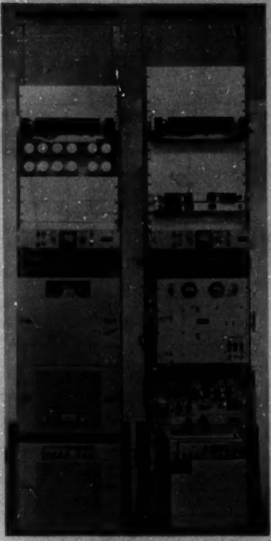

Fig. 14. Two type-72B transmitters multiplexed on common antenna. Multiplexer filter panel mounted near top of transmitter rack on left-hand side

DIPLEXING

To allow simultaneous operation on a single antenna of a transmitter and a receiver (diplexing), the filter arrangement shown in Fig. 15 is commonly used. The recommended minimum frequency separation between transmitter and receiver is 12 mc. The primary purpose of the transmitter filter is to prevent the transmitter from loading the antenna at the receiving frequency. A 2-section filter having an attenuation of 25 db at the receiving frequency and an insertion loss of 0.5 db provides the necessary isolation.

The receiving filter must, in addition to preventing receiver loading of the antenna at the transmitting frequency, provide sufficient isolation between the transmitter and receiver to prevent the creation of objectionable modulation products in the front end of the receiver. Such

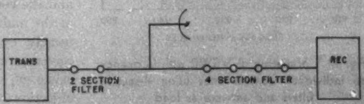

Fig. 15. Block diagram showing filter arrangement for diplexing

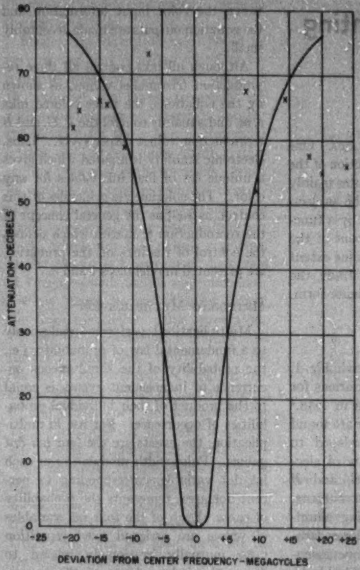

Fig. 16 (left). Attenuation versus frequency characteristics of 4-section filter. Crosses show required attenuation when diplexing

modulation products are primarily difference frequencies between high-order harmonics of the local oscillator mixer injection frequency and of the transmitter frequency. For example, when the transmitting frequency is lower than that of the receiver and the difference between them is equal to one-half the receiver intermediate frequency, a product is created in the first mixer stage between twice the transmitting frequency and twice the injection frequency. This product is equal to the intermediate frequency. There are numerous other discrete frequency combinations which will result in objectionable interference unless sufficient isolation is provided.

The interfering effect of the frequencies within the operating range of the receiver, and the isolation required between the transmitter and receiver determine the attenuation required to the transmitter. This requirement is shown in Fig. 16 on the same co-ordinates as a curve showing the attenuation provided by the 4-section receive filter. Fig. 17 shows a duplex transmitter-receiver assembly mounted on the same rack; the diplexer is mounted near the top of the rack immediately below the terminal block.

MULTIDIPLEXING

A frequently used combination of equipment, two transmitters and two receivers, may be operated on a single antenna through use of a multidiplexer; a combination of a multiplexer and a diplexer. The necessary filter characteristics for this arrangement may be obtained through analysis of the requirements for both the multiplexer and diplexer. Fig. 18 shows a photograph of two transmitters and two receivers which will be connected to a common antenna through the multidiplexer mounted near the top of the dual receiver rack. Four-section filters are used on the receiving lines and 2-section filters on the transmitting lines; the minimum frequency separation between a transmitter and a receiver is 12 mc; between receivers, 6.3 mc, and between transmitters, 7.5 mc. The spacing between transmitters could be reduced to 6.3 mc through use of 4-section filters on the transmitting line; however, this results in an unwieldy mechanical arrangement not conducive to convenient connection at the common junction block.

Electronic Computer for Color Printing

H. E. ROSE
NONMEMBER AIEE

PROBLEMS of color deficiency have been associated with color photography and magazine printing for many years and, more recently, with color television. The development of the additive and subtractive color theories in which the reproducing primaries are related to the spectral sensitivites of the 3-color-separation photographs, has been described by Hardy and Wurzburg, Jr.[1] A basic relation between the additive and subtractive contributions of the common printing process for a 3-color process was published in the same year.[2] The equations derived relate the transmissions of the 3-color-separation photographs to a function of the amounts of the inks and their tristimulus values. With the daily production of millions of magazine issues in the United States using a fourth (black) ink, compared to the smaller editions in Europe for which these equations apply, a modification to the equations was necessary to include the effect of the black ink used in the high-speed printing methods in this country. These final equations for color correction were published in 1948.[3] Where **V** is the vector of the red (*R*), green (*G*), and blue (*B*) tristimulus values of a color and the subscripts of **V** are the tristimulus values for the paper, full inks and full over prints of inks, the equation for the percentage of cyan (*c*), magenta (*m*) and yellow (*y*) inks is

$$\begin{aligned}\mathbf{V}=&(1-c)(1-m)(1-y)(1-n)\mathbf{V}_w+\\&c(1-m)(1-y)(1-n)\mathbf{V}_c+m(1-c)\times\\&(1-y)(1-n)\mathbf{V}_m+y(1-c)(1-m)\times\\&(1-n)\mathbf{V}_y+cm(1-y)(1-n)\mathbf{V}_{cm}+\\&cy(1-m)(1-n)\mathbf{V}_{cy}+my(1-c)\times\\&(1-n)\mathbf{V}_{my}+cmy(1-n)\mathbf{V}_{cmy}+n\mathbf{V}_n \quad (1)\end{aligned}$$

As simultaneous equations, with the ink percentages as implicit functions of the *R*, *G*, and *B*, color tristimulus values, they are as yet indeterminate with four unknowns and three equations. One unknown *n* can be made a function of the other three because it contributes mainly to the luminance control of the subject. Thus, with *n* being generated by a function of the luminance component of the other three inks, modified to some extent by preferences of the printing trade, the equations reduce to a determinate form.

Computer System

The computer system is shown in Fig. 1. The method of solving the equations for color correction was published in 1948.[4] Greater stability and accuracy are found in the present computer developed to solve faster for the higher rate of electronic scanning. Input *R*, *G*, and *B* signals have current generator outputs. They are derived by scanning simultaneously the *R*, *G*, and *B* color separations by a flying-spot technique essentially as described by Haynes.[5] The blocks marked *R′*, *G′*, and *B′* include the multiplication and summation of the right-hand side of the equations. Actually, the quadruple products of the ink values are derived and multiplied by three normally different values of subscripts of **V**. These are then summed in their corresponding *R′*, *G′*, and *B′* groups along with the $n\mathbf{V}_n$ terms. The *R′*, *G′*, and *B′* are compared to the *R*, *G*, and *B* signals by the e_r, e_g, and e_b units respectively and these error signal outputs control the ink generators so that the differences between the color input information and the equation outputs are made acceptably small.

Although all inks control all three reproduction tristimulus values, as shown by the equations, the three colored inks *c*, *m*, and *y* mainly control the *R*, *G*, and *B* reproduction values respectively. Thus, electronic stability is assured which gives a unique set of four ink values for any color. The colorimetric principles of this control, as well as the general concept of the reproduction primaries which defines the control of the inks on the primaries, are presented in references 1 and 3.

Method of Multiplication

Multiplication is performed analogously to a fundamental law of probability, i.e., the probability of the simultaneous occurrence of independent events is equal to the product of their individual probabilities of occurrence. For use in multiplication, the events are the four ink-dot values. Pulse-width modulation of each ink-dot variable, corresponding to percent dot area, represents the probability of each. Each of the four ink variables of pulses are assigned fixed repetition rates mutually irrationally related to insure the independence of the events. Just as in probability, where a large number of trials is necessary, the coincidence of the ink signals must be averaged over a long time. The time for scanning a unit area of picture must encompass many of the coincidence pulses. The scanning speed and size of the unit area determine this time to be about 100 microseconds. To resolve the area, the computer must be appreciably faster by being stable in at least 50 microseconds. The repetition rates of the four inks are assigned between 230 and 131.5 kc so that

Paper 55-180, recommended by the AIEE Computing Devices and Instruments and Measurements Committees and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted August 5, 1954; made available for printing January 11, 1955.

H. E. Rose is with the Radio Corporation of America, Camden, N. J.

The author is indebted to C. B. Kinne, formerly of the Interchemical Corporation, for many suggestions during the initial development and to H. J. Woll, Radio Corporation of America, for suggestions on analytical approaches.

15 cycles of the lowest frequency occur in the unit-area time.

Ideally, the repetition rate should be very high so that in a fixed unit time for computer solution many more than the 15 cycles of the lowest frequency are within the unit time. However, another specification for the system performance is that a 1-per-cent pulse width, representing 1 per cent of the ink value, should be capable of being reproduced electrically. This determines the rise time of the signals supplying the multiplication networks which, for the highest repetition rate of 230 kc, is 1 per cent of the period of 4 microseconds or 0.04 microsecond.

Fig. 2 shows the multiplication circuit, the ink tristimulus value generators, *V1* and *V2*, the summation method, and the error signal unit. Starting with the ink dot *C* and reverse $(1-C)$ ink-dot generator, for the *C* values at the left, groups of four diodes each are shown receiving signals from the ink and reverse ink signal matrix of horizontal signal lines. Whereas all the reverse values are fed to the white group of diodes, the *C* group, for example, is the same except that *C* is used instead of the reverse *C* value. Other groupings are used until all the terms are available.

Each group of four diodes will then develop one of the products of the ink factors in the four color equations. The diode configuration will generate an output voltage at ground potential only when all inputs are at ground potential. Because the fraction of time that each signal is at ground is made equal to the ink-dot value, the average output value will be the product. Before filtering the output of each, which would give the average value required, the output of each group is fed to grids of three pentodes. These gate on to a current, assigned by the cathode resistor, which are the *R*, *G*, and *B* filter-emulsion constants for that ink. These output-current pulses are then summed by paralleling all plates for the appropriate color equation. These are then integrated in a single capacitor, one for each equation summation. Integration prior to this point would not allow the summing tubes to operate on an on-off condition. Thus, linearity demands on tube characteristics are avoided. Variations in tube emission are minimized by the heavy cathode degeneration developed by the controls for the *R*, *G*, and *B* constants.

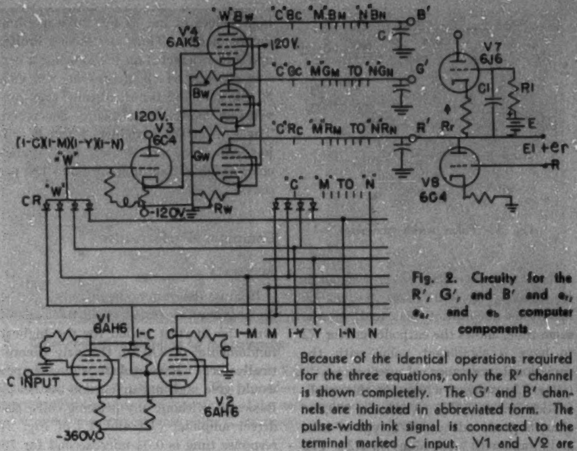

Fig. 2. Circuity for the R′, G′, and B′ and e_r, e_g, and e_b computer components

Because of the identical operations required for the three equations, only the R′ channel is shown completely. The G′ and B′ channels are indicated in abbreviated form. The pulse-width ink signal is connected to the terminal marked C input. V1 and V2 are push-pull power stages to drive the diode product generators "W," "C," and "M" to "N." The (1−M), M, (1−Y), Y, (1−N), and N signals are generated by stages identical to V1 and V2. Paper and ink color separation values are entered by the controls R_w, R_c of the stages similar to V4 to produce the equation terms WR_w, CR_c, etc.

PULSE-WIDTH SIGNAL GENERATORS, AMPLIFIERS, AND COMPARISON CIRCUITS

The conversion to a pulse-width signal from the error signal unit is accomplished by adding the signal voltage to a saw-tooth voltage wave form of fixed frequency and then referencing the sum with respect to the critical voltage of a trigger circuit. With the sum above the critical voltage, the trigger circuit is forced to one of its stable conditions. Below the critical voltage, the other stable condition occurs. A differential between the ON and OFF critical voltages is made to be somewhat less than 1 per cent of the saw-tooth height so that stable 2- and 98-per-cent pulse widths are available.

Fig. 3 shows a crystal-controlled oscillator synchronizing each of the saw-tooth generators to one of the four irrationally related frequencies required in the multiplication method. The high stability in the saw-tooth amplitude is mainly the result of the manner of operation of the half of tube *V4* marked "*B*". The output-wave amplitude is essentially equal to the difference in plate voltage between its two states; it is either cut off or gated on to a current under heavy cathode degenerative feedback. Capacitor *C* is charged to a fixed potential in a short time and discharges 25 volts through *R1*. *R2* and *R3* sum the input signal and the saw-tooth which is then referenced to the trigger circuit input at *V5* grid. Tubes *V5* and *V6* operate as a bistable circuit because of controlled, regenerative feedback to the screen of *V5*. The halves of *V6* are either conducting or nonconducting. Just as with the saw-tooth generator, this type of operation assures reliable levels of operation. The coupling circuit between *V3* and *V5* maintains adequate transient response and eliminates grid current effects on the saw-tooth wave form.

The circuits for the push-pull output stage of Fig. 2 and the d-c amplifier developing the amplified error signal are commonly used types of circuits. The amplifier features a gain of 50 and a −3-decibel response at 1 megacycle with a 2-tube subminiature cathode-coupled input stage followed by a cathode-coupled dual triode stage. Referred to the input of the amplifier, the drift is less than 2 millivolts over 1 hour after warm-up time. One hour is equivalent to 1 complete operation cycle of the apparatus.

The error signal is derived by providing a high variational resistance to the input- and output-current generators. Fig. 2 shows one of the circuits in detail for the *R* and e_r channels. With a signal of opposite polarity to *R* supplied to *V8* by an amplified multiplier phototube signal, the integrated current *R′* and $-R$ plate current of *V8* add to give a constant sum for perfect solution of the equation. An error signal output e_r will be generated for an inequality of the equation depending upon the variational resistance seen at the e_r signal line. This resistance is effectively increased by using *V7* as a

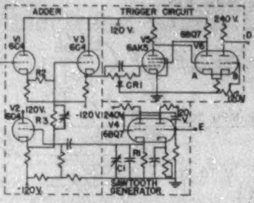

Fig. 3. Pulse width generator

cathode follower with the error signal as its floating ground. The battery *E* maintains a constant bias and, at the same time, allows the cathode resistor *R2* to have a significant value with the variational resistance of predominantly $(1+\mu)R2$ resulting, where μ is the amplification factor of *V7*. A value of 200,000 ohms is produced by a *6J6* type of tube as *V7*, and with 7,000 ohms for *R2*. The miniature, 45-volt battery operates at practically zero load.

BLACK-INK SIGNAL GENERATOR

The function required to generate a black-ink signal is shown in Fig. 4 where *C*, *m*, and *y* ink values are connected to two sets of limiters. The upper set limits the ink values individually to a value slightly in excess of maximum values of the three colored inks used with solid black ink to make the darkest color in the picture. High-speed printing usually assigns a total of 260 per cent of ink made up of 100 per cent black ink and 160 per cent divided almost equally among the three colored inks. Thus, ink values above approximately 53 per cent, which normally contribute towards saturation, are effectively eliminated as control factors in black-ink generation. The arithmetic adder 1 then provides a sum of ink values from which an amount may be subtracted equal to the amount of three-color black that may be desirable before black ink is to be allowed. The second limiter provides the solution to the problem that the last mentioned sum tends to generate as much black for two high values of ink as for three medium values of ink. Thus, the second limiter and adder detect if an ink is below a certain amount which, if present, will gate off the gate and threshold unit, thus preventing black from being generated. The gain of the amplifier *A* can be adjusted to give any desired total undercolor of ink within limits of 60 to 180 per cent.

Computer Performance

ACCURACY

Because the gated output pulses of the diode groups represent small fractions of even the shortest period for the highest fundamental of 230 kc, the only theoretically true rectangular wave shapes would give high multiplication accuracy. Basically, without any peaking coils, the driver amplifier (*V1* and *V2* of Fig. 2) response time is 0.04 microsecond for 70 per cent of full amplitude. A serious loss would occur, however, in the peak pulse output because of the exponentially changing wave form. Peaking coils, giving 5-per-cent overshoot, reduce product errors by a factor of 3 in the pulse-width region below 3 per cent. Products of three signals, two at fixed 50-per-cent pulse widths and the third of variable pulse width have been measured to be within 1-per-cent accuracy, with the greatest error occurring in the region below 3-per-cent pulse width of the variable signal.

Accuracy of computing is measured by the difference between the input color signals and the equation values for the ink colors. This difference must be held to a low value with respect to the *R*, *G* and *B* color separation values. Because the trichromatic coefficients are the ratio of the three filter-emulsion values, chromaticity values are independent of the brightness. Color accuracy is then most difficult for low-brightness colors, where the absolute values are in the order of 4 per cent. The specification of accuracy in this apparatus has been assigned to be such that a 1-per-cent difference in the trichromatic coefficient should be resolved. Then considering the low-brightness value of 4 per cent, the *R*, *G*, and *B* equations must be capable of being solved to an accuracy of 1 of 4 per cent or 0.04 per cent of their full range. The error signal outputs, described in the foregoing and derived by tube *V7* of Fig. 2, as well as the amplifier gain and duty-cycle generator will provide this performance.

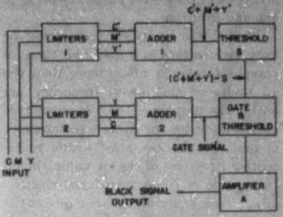

Fig. 4. Black-ink signal generator

A significant contribution towards accuracy is the extensive use of the on-off type of operation of tube circuits. This has been described as the basis of multiplication and of the pulse-width ink generators. The entire computer is supplied by electronic regulated power supplies, so that the remaining d-c amplifiers have a stable reference. The over-all computer accuracy is given by a tolerance of ±2.5 per cent in the ink values.

SIGNAL/NOISE RATIO

In any such pulse-width modulation information signal, a Fourier series specifies the fundamental and harmonic content. Four such pulse-width signals, modulating one another, will give rise to frequency terms of the fundamentals, beats of the fundamentals, and of all combinations of their harmonics. The Fourier coefficients reduce rapidly with the number of the signals and inversely proportional to the product of the harmonics of the individual frequencies. A single pulse-width-modulated signal is described by the equation

$$F_1(t)=c+\sum_{i=1}^{\infty}\frac{2\sin \pi ic}{\pi i}\sin iW_1t \tag{2}$$

where

c=fractional pulse width
i=harmonic

Multiplying four such functions of W_1, W_2, W_3, and W_4 frequencies with i, j, k, and 1 harmonics respectively gives the form of

$$F(t)=F_1(t)F_2(t)F_3(t)F_4(t)=cmyn+F(w) \tag{3}$$

Table I. Fourier Series Expansion of Modulation Products

Frequencies	General Expression of F(w)	Maximum Value
iW_1	$\frac{2myn\sin(\pi ic)}{\pi i}$	$\frac{0.637}{i}$
iW_1-jW_2	$\frac{2yn\sin(\pi ic)\sin(\pi jm)}{\pi^2 ij}$	$\frac{0.202}{ij}$
$iW_1-jW_2+kW_3$	$\frac{2n\sin(\pi ic)\sin(\pi jm)\sin(\pi ky)}{\pi^3 ijk}$	$\frac{0.0643}{ijk}$

Fig. 5. Color correction supplied by the computer

Left: print of red separation negative. Center: print of the recorded, corrected C negative. Right: the computer correction mask is a unity-gamma photographic print of the composite of the first and the negative of the second. This procedure presents the computer's correction in a visual manner so that the density variations of the mask compared to the density of the lower step of the mask's gray scale determines the ratio of the corrected value to the uncorrected value of the C information

where $F(w)$ is a function of frequency, as shown in Table I, for all the frequencies and expressions of the terms for those frequencies.

The greatest amplitude occurs when, e.g., in the second row sin ic and sin jm both equal unity. This occurs when the harmonic factors i and j are equal to 1. The other two ink-dot value factors of c and m give the greatest amplitude when they are equal to 1/2.

Fortunately, because of the relatively low signal range of approximately 26 decibels for the process, it was found empirically that the coefficients below 0.02 may be disregarded. Where in row two, frequencies of beats of harmonics up to a product of ten are shown to contribute, row three indicates that harmonics only up to a product of four need be considered. These then, for the four frequencies used, show no more than 5-per-cent amplitude in the range of direct current to about 10 kc. Since these occur under unique values of colors, the average beat is of less than 5-per-cent amplitude. In fact, the peak-to-peak noise of the computer with the inks adjusted for maximum noise is less than 3 per cent or greater than 30 decibels down from the full signal. Although this signal-to-noise figure does not compare with those of most audio equipment, corrected plates recorded show no significant degradation of picture quality.

FREQUENCY RESPONSE

Speed of computation is established so that detail loss in the final photographic recording is not significantly attributable to the computer. As pointed out before, the time for scanning a unit area is 100 microseconds. Since a complete change of information may occupy this time, in order not to suffer detail loss the computer should become completely stable at both levels of the signal. A decision was made to provide aperiodic response to the input signal which is conveniently gained by having only a 6-decibel loss per octave in the computers frequency range. Thus, specifying that the response is to be within 2 per cent of its final solution for one-half the unit area time means that the −3-decibel response must be for a frequency of 13 kc. The 2 per cent of final solution figure was chosen so that the logarithmic recording on photographic materials of the transient response is not deteriorated in density by more than 10 per cent; i. e., although a voltage decreases to 2 per cent of its final value in 50 microseconds, the transient is recorded on the photographic plate to only 90 per cent of the full range of density available. It has been estimated that this loss is all that may be tolerated visually in order not to lose significantly on resolution.

The equivalent circuit of this computer can be shown to be simply the parallel combination of the two current generators R and R', the variational resistance R_r of the error signal unit ($V7$ resistance of Fig. 2), and the capacitance C of Fig. 2. An equivalent conductance K converts the error signal voltage e to produce the ink value which is returned to the R' generator. Also cross coupling exists between the m, y, and n ink generators to the R' generator. Therefore, the feedback loop contains a variable gain factor g which varies from near zero to near unity, depending upon the color region and the luminance value being computed. Neutral grays give the larger values of g which give a −3-decibel response frequency of 13 kc. This frequency may be shown to be

$$W_0' = KgRW_0$$

where

$$W_0 = 1/CR_r \qquad (4)$$

Fortunately, this high speed neutral gray and lower speed chromaticity computation is analogous to the sensitivity of the human eye. Just as in both the fields of color television, and color printing, the black or luminance information is considered a detail function or key plate. Although the conclusion may be drawn, therefore, that a recorded colored ink plate will not have the familiar photographic sharpness of detail in all colors, the 4-color printed proofs show acceptable visual resolution.

Conclusions

A number of conclusions may be presented from the description of the computer and from the experimental use in the printing trade.

1. An electronic computer has been described which solves three 4th-degree simultaneous equations in less than 50 microseconds to establish the four ink values of color printing required to match the color of the original picture.
2. A novel method of multiplication has

been analyzed for which simple circuit components perform with 1-per-cent accuracy.

3. Freedom from drift and accuracy is improved by the extensive use of the on-off, digital type of operation for vacuum tubes in the computer components. The computer accuracy will remain within ±2.5 per cent for a period of time greater than the cycle of operation required in producing the color-corrected plates of a subject.

4. Experimental use for a period of about 5 years has proved its usefulness because the parameters of the color input information system and the final processing steps of the plates required to make a printed proof have been considered.

5. Fig. 5 indicates the significant contribution of this system.

Open-Wire Carrier Systems in South Africa

C. F. BOYCE
NONMEMBER AIEE

THE UNION of South Africa and the neighboring mandated territory of South-West Africa occupy an area of about 800,000 square miles at the southern tip of Africa, about a quarter the area of the United States. It is a land of vast mineral wealth, and the world's chief source of gold and diamonds. Exceptionally rapid industrial development has characterized its cities during the past 20 years.

About a quarter of the total population of 14,000,000 live in the major cities and adjoining areas, shown in black in Fig. 1. The balance of the population is somewhat unevenly distributed throughout the country, and in towns, none of which have a greater population than 50,000. About one-fifth of the total population is of European descent.

The climate is in general a temperate one. A long range of mountains roughly parallel to the coast divides the coastal strip from the high plateau which forms a large portion of the total area of the country. Much of this plateau has a dry climate not unlike that of Southern California and New Mexico. The mean annual rainfall for South Africa is 25 inches, varying from 5 inches in the west to about 70 inches in parts of the eastern coastal zone.

There are nearly 600,000 telephones in South Africa, and of these just over two-thirds are dial telephones. All of the latter are in the nine major cities. The balance of the telephones are mainly of the local battery type employing 17-cycle-per-second (cps) signaling.

Within the areas shown in black in Fig. 1, telephone circuits are provided by underground cables, including carrier-on-cable and coaxial cable systems.[1,2] Outside of these areas all toll circuits are provided by open-wire routes and carrier systems on these routes. This paper deals with these open-wire toll telephone circuits and associated broadcast and telegraph circuits.

Growth and Present Size of Carrier Network

About 30 years ago, the first carrier systems, which were of the single- and 3-channel types, were installed in South Africa.[3,4] The subsequent growth in carrier telephone circuit mileage is illustrated in Fig. 2. The growth in carrier telegraph circuit mileage, i.e., voice frequency telegraphs employing carrier channels as bearer circuits, and carrier telegraphs (generally known as high-frequency or HF telegraphs) in the frequency range of 6 to 30 kc per second is shown in Fig. 3. There are about 600 carrier systems of various types in service, varying in length from 15 to 1,100 miles. The numbers of carrier toll telephone circuits on the main backbone routes only are shown in Fig. 1. In addition to these, carriers are extensively used on secondary routes.

The Scope of Open-Wire Carrier Systems

The minimum line length for which carrier exploitation appears to be economical on open wires depends on several interrelated factors such as the number of channels, the relative costs of the terminal equipment, the line, accommodation, availability of power and maintenance staff, etc. In some cases this minimum length may be as low as 10 to 15 miles. Frequently when a route cannot accommodate additional wires, the use of carrier systems is the only practicable method of increasing the circuit capacity. In general, for distances greater than 30 to 40 miles, and where the circuit growth is such that not more than about 200 circuits are likely to be required at the end of 20 or 25 years, an open-wire route with carrier systems may well prove to be the most economical solution, on a "present value of annual charge" basis.

The maximum number of telephone circuits at present provided on a single open-wire route is between 200 and 240. It is proposed to increase this figure in the near future, for distances up to 150 or 200 miles, to about 350 circuits, with the aid of compandors. This aspect is dealt with later in more detail.

Equipment Features

The principal features of open-wire carrier systems, many of which were first developed in the Bell System, are well known. Only those features which may differ from those employed elsewhere will be mentioned. The line and principal modulating frequencies of the systems used in South Africa are shown in Fig. 4. Several of these systems have been

Fig. 1. Open-wire carrier telephone circuits in South Africa, on main lines only

Figures indicate the number of channels planned for 1958

described in various technical publications.[4-6]

Frequency Translation

Up to 1940 all systems employed modulation methods which translated individual channels direct to the required line frequency. Most modern systems employ one or more stages of group modulation, the advantages of which are well known. In the case of the *SOJ* 12-channel system, which is very similar to the *J* system of the American Telephone and Telegraph Company, the basic group of 12 channels is translated to the frequency range of 60 to 108 kc per second in one stage, employing crystal channel filters.[7] This base group is common to cable systems and much use is made of the facility to switch 12-channel groups without demodulating to voice frequencies.

Carrier Supplies

Single- and 3-channel systems employ inductance-capacitance oscillators individual to each channel. In practice these are found to be sufficiently stable to maintain channel synchronization to within 2 or 3 cps over periods of several months, particularly the more modern temperature compensated types. Individual channel oscillators render equipment more flexible, but in the case of a 12-channel system there are economic and technical advantages in employing a common crystal-controlled master oscillator in conjunction with harmonic

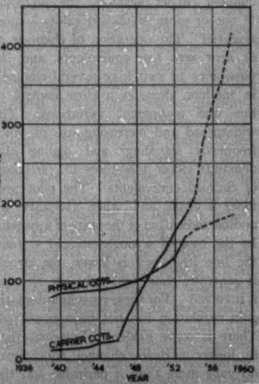

Fig. 2. Growth of toll circuits in South Africa: trunk circuit mileages

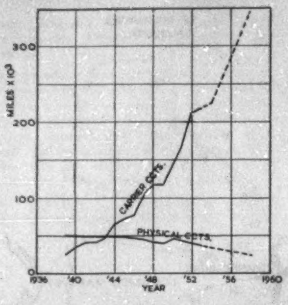

Fig. 3. Growth of telegraph circuit mileages in South Africa

generators. Where there are more than two or three 12-channel terminals, an appreciable saving in cost may be effected by employing a carrier supply system common to several terminals. In this event a duplicate carrier supply set with automatic changeover facilities is desirable. The provision of a pilot frequency to keep the two terminals of a system in synchronism has not proved to be necessary.

The earlier voice frequency telegraph systems employ multifrequency generators. These require skilled maintenance and a duplicate machine in instant readiness, since the speed of such machines must be maintained within very narrow limits. Separate oscillators for each channel have proved to be a more satisfactory solution.

Automatic Gain Regulation

With the possible exception of single-channel carrier systems, the provision of one or more regulating pilots is most essential. The operation of channels at or near zero loss equivalents, and the possibility of switching several channels in tandem, demand a close control of line and equipment variations. The widespread and increasing use of voice frequency signaling[9] and dialing also demands closer tolerances in variations of channel equivalents. The pilot provides a visual and, when necessary, an audible indication of the state of a system. In the case of a single-channel system, the line frequency is lower, the circuit is generally short and only one channel is involved. For these reasons automatic gain regulation has not been employed. There is some evidence, however, that in longer systems channel equivalents do vary more than is desirable and the provision of a pilot would also provide a system failure alarm.

On 3-channel and broadcast carrier systems a single pilot in each direction is provided. On the more modern systems, this pilot provides a measure of slope as well as flat loss adjustment, by means of a thermistor in an equalizer. On the 12-channel system, the greater frequency spread requires the use of two pilots at or near the ends of the transmission band.

On systems with more than two or three repeaters, it is necessary to ensure, by careful design, that the regulators do not "hunt." On long systems it is also desirable that repeaters should restore to their correct gain after a break in the transmission path without undue delay, since restoration delays at successive repeaters tend to be cumultative, and therefore extend the duration of short breaks.

Broadcast Carrier Systems

There are three broadcast programs in South Africa and for each of these a 2-way carrier circuit is provided between each two of the principal cities shown in Fig. 1, with the exception of Windhoek. Forty carrier systems provide 9,500 miles of 2-way program circuit. The network is essentially a "ring main," since each studio is able to receive on each of the three programs from each of two different directions. The line frequencies correspond to the 3-channel spectrum. The channel equivalent is maintained constant within 1 decibel (db) over the frequency range of 30 to 10,000 cps. The suppression of the unwanted side band is achieved by combining the output of two modulators, in one of which the phase of both the program input and the carrier has been displaced by 90 degrees relative to the other modulator.[4] Both the noise and the distortion products of the channel are of a very low order. At intermediate studios which normally accept, and only occasionally originate, programs, the program is received "in tee" from a repeater to avoid introducing the effects of local cables. Facilities are provided so that the studio can at any time convert the repeater into two terminals and so originate a program.

Rural Carrier Systems

Apart from the main routes, carrier systems have played a vital role in providing toll circuits in rural areas. Although farms tend to be large and the population density low, most areas require telephone service at intervals of the order of 10 miles or less. Single- and 3-channel systems are extensively used to provide toll lines. One version of the single channel system (*SOC* system) employs an inert terminal requiring no power, a most useful feature in many remote areas. In this system the active terminal transmits the carrier which is voice modulated at the inert terminal to provide the return path. A 2-channel version of the same system has recently been introduced. The range of the inert system is limited and the high level of carrier transmitted normally limits its application to one system on a route. It is hoped that the transistor will make it possible in the near future to provide a rural system in which the remote terminal is supplied from a small dry battery or fed with power over the line. Such a system will probably be arranged so that channels may be added one at a time with the channels from the exchange terminating at different points. The system will probably employ 6 or 8 kc per second spacing between the channels. If the cost proves to be sufficiently low such a system may be used for providing customer as well as toll lines.

Carrier Telegraph Systems

The voice frequency telegraph systems are based on a 120-cps spacing and provide 24 channels capable of transmitting at a speed of 50 bauds with low distortion. The so-called HF telegraph systems provide up to six or eight telegraph channels in the 3-channel carrier range; see Fig. 4. This system has proved most useful in providing small numbers of telegraph circuits to small towns in conjunction with 3-channel carrier telephone systems. The earlier *TOB* system is essentially separate from the 3-channel telephone system, whereas the later *STO* type employs some equipment which is common to the *STO* telephone system.

All the systems, which are of the amplitude-modulated type, use rectifier modulators at the transmitting end and telegraph relays at the receiving end. Trials on frequency-modulated telegraph systems indicate that they are considerably less affected by short sudden changes of level. Frequency-modulated systems are, however, considerably more costly, bulkier and somewhat more complicated, and their use on stable high-quality bearer channels has not, up to the present, been justified.

Equipment Practices

The design of carrier equipment in regard to the quality of components, methods of mounting and wiring, long-term stability, ease of maintenance, and the saving of space has for many years

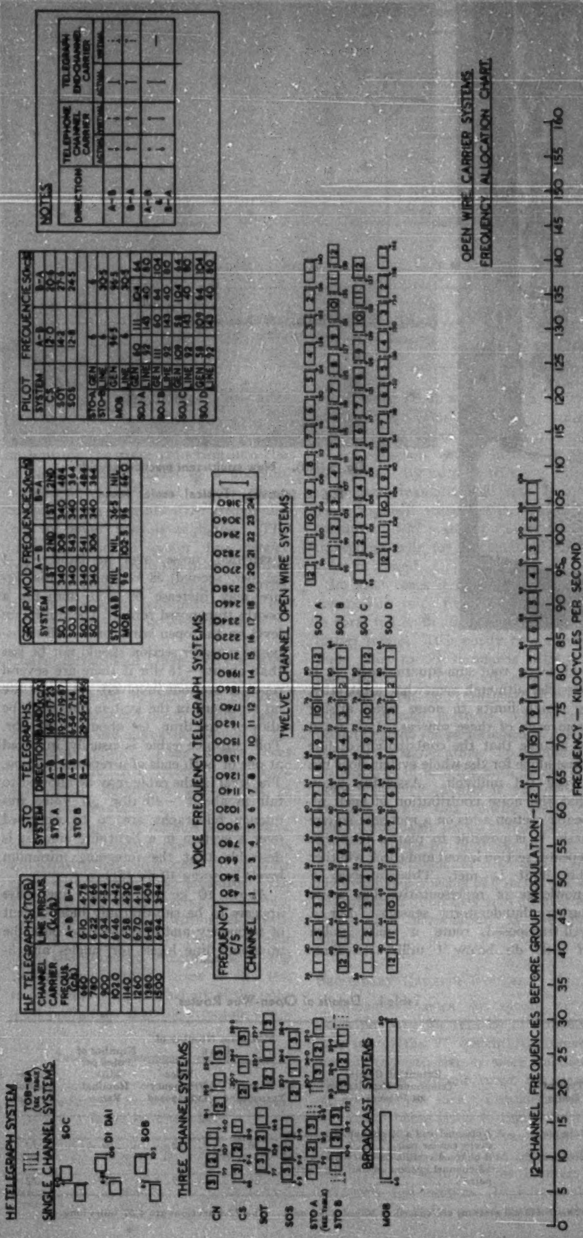

Fig. 4 (left). Line frequencies used in carrier systems

received close attention and the latest equipment reflects considerable advances in all of these respects.[10,11] The new equipment, which has been standard for the past 6 years, features light frameworks of welded folded steel sections. The slide-in equipment panels are located in the framework by means of die castings attached to each side. These castings mount terminal blocks for the bay wiring which fall opposite similar blocks in the panels, to which connection is made by suitable links. Part of a bayside is shown in Fig. 5.

The most striking change in the newer equipment is the great reduction in size, frequently to a third or a quarter of the previous figure. The limits to progress in this direction are set by maintenance considerations and heat dissipation. The reduced height has been of considerable benefit in installing the equipment in buildings not originally intended for equipment. The weight per foot run of the new bayside is some 30 per cent higher than that of the old, but this has not proved to be of any consequence. Shipment is made with the framework and panels packed separately in one case. This makes for great ease in handling since the heaviest component, the bay framework, weighs only about 100 pounds.

Installation testing and adjustment as well as maintenance procedures have been simplified. Panels can be quickly removed for inspection or replacement. All units requiring adjustment are arranged on the front of the panel. In addition to testing points on the bay-panel links, at which both terminated and level measurements may be made, important points are brought out to auxiliary terminal strips on the face of the panel, thus giving access for measurement without unsoldering wires. A centralized valve failure alarm panel enables space currents to be measured with facility and also provides a continuous monitor on space currents. Should any valve space current fall below a preset value, an alarm is operated.

Components may be sealed either individually and then mounted in a dust proof can, or alternatively assembled without individual seals, in hermetically sealed cans filled with dry air. The latter procedure is frequently cheaper in manufacture but does necessitate arrangements at central depots for the opening and repair of cans under skilled supervision. Experience has shown that

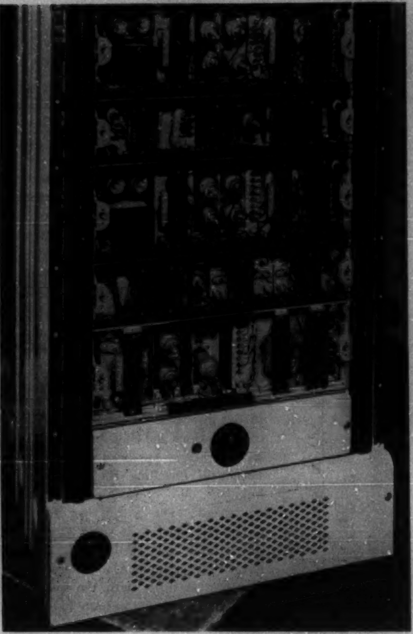

Fig. 5 (left). New equipment practice bayside

Fig. 6 (above). Typical carrier route

Vol. 7
Pt. 1
1955

the percentage of faulty cans is low, and faults occur mainly during installation. In general, only cans which contain critical components likely to be affected by humidity variations should be sealed. All equipment is wired either with polyethylene-insulated wire or where permissible polyvinyl-chloride-insulated wire.

The Siting of Carrier Repeater Stations

Since single- and 3-channel systems today rarely involve a repeater, the siting of repeater stations is mainly associated with 12-channel repeaters. The maximum line-transmitting level per channel is +17 db relative to the switchboard test level (dbr). The minimum level is set by noise considerations. A maximum noise voltage of 1 millivolt as measured on a European International Consultative Committee on Telephony psophometer and telephone weighting network measured at the 2-wire end of the circuit is permitted. This noise is made up of equipment noise, crosstalk from other systems on the route, and atmospheric or static noise. On the assumption that the various noise levels add on a root-sum-square basis, it is possible, although somewhat arbitrarily, to assign limits to noise levels arising from each of these sources. It is usual to assume that the contribution of line noise alone for the whole system does not exceed 0.3 millivolt. Assuming again that the noise contribution of each repeater section adds on a root-sum-square basis, it is possible to plan a tentative repeater section layout and check whether this limit is met. This involves a knowledge of representative line noise during thunderstorm seasons. For a well-transposed route a noise value of −85 db below 1 milliwatt (dbm) (weighted noise over a band of 4 kc per second) is assumed. This figure may increase to −70 dbm for a poorly transposed route. The minimum level on the open wires on a well-transposed repeater section should not be less than about −15 dbr if there are several repeater sections involved. If there are no repeaters in the system this may be allowed to drop to about −20 dbr. Toll entrance cable is usually involved at one or both ends of a repeater section. The level in the cable may be allowed to fall to about −40 dbr. If voice frequency telegraphs are to be operated over a system in a lightning area, it is desirable that the foregoing minimum levels be some 10 db higher.

Above 10 kc per second, line noise appears to be substantially independent of frequency and it is usual to base the minimum line levels for single- and 3-

Table I. Details of Open-Wire Routes

Type of Route	Extent of Carrier Telephone Exploitation at Present	Maximum Number of Pairs		Number of Poles per Mile, Nominal Value	Transposition System
		Carrier Transposed	Voice Frequency Transposed		
Main line	A 3-channel and a 12-channel system on every carrier pair	16	12	40	*J3*
Secondary	A 3-channel system on every pair and a 12-channel system on half the carrier pairs	16	12	28*	*J2*

* The fractional sections are spaced at 40 poles per mile. The *J2A* sections are 4.57 miles long.

Table II. Wire Configuration, Open-Wire Main-Line and Secondary Routes

Types of Pairs	Pairs per Arm	Spacing Between Wires of a Pair, Inches	Distance Between Centers of Horizontally Adjacent Pairs,* Inches	Distance Between Arms, Inches
Carrier pairs, to 1953	4	8	23	24
Carrier pairs on 40-pole-per-mile routes after 1953	4	6	26	24
Voice-frequency pairs	6	6	13	12†

* Pairs on either side of the pole are spaced 24, 23, and 23 inches respectively.
† The voice frequency arms are always below the carrier arms and 24 inches from the nearest carrier arm.

Table III. Fine Weather Copper-Wire Attenuation per Mile for 8-Inch Spacing, Db

Diameter, Inches	Pounds per Mile	10 Kc	30 Kc	90 Kc	150 Kc	270 Kc
0.137	300	0.070	0.120	0.208	0.271	0.34
0.112	200	0.087	0.144	0.245	0.317	0.40

channel systems on the same figures as given. The separation between open-wire telephone and power routes is based on limiting the noise induction into the physical or audio circuit to 1 millivolt (weighted value)[12] and under these conditions the noise at carrier frequencies due to power lines is negligible. The increasing use of power line carrier systems has not up to the present caused any interference to telephone carrier systems, but the possibility of its occurring should not be overlooked.[12]

Characteristics of Open-Wire Routes

The principal physical and electrical details of standard South African open-wire routes are given in Tables I, II, III, and IV.[4,8,12] Their design owes much to the Bell System[14] but there are certain differences arising out of local circumstances.

Since supplies of suitable local timber are not yet adequate, most carrier routes are constructed with steel or concrete poles with tubular steel crossarms. To maintain the wire spacing accurately, the arms are braced with steel straps; see Fig. 6. The arm (7 feet) is shorter than the standard American arm and the distance between arms is also less in order to reduce the height of the pole. This has meant that the crosstalk couplings are some 6 db worse than in American practice. This has been compensated on main lines by the use of the *J3* transposition system instead of the *J2* system. By keeping wire sag differences and irregularities in span lengths down to small values, it is possible to operate an *SOJ* system on every carrier transposed pair for distances of 1,000 miles or more.[3]

Table IV. Maximum Crosstalk

Worst Crosstalk Between Carrier-Transposed Pairs per Repeater Section Over the Frequency Range Indicated, Db

Type	10 to 150 Kc	150 to 250 Kc
Far-end	55 to 70	35 to 45
Near-end	40 to 65	30 to 45

In most cases it is necessary to accommodate voice frequency pairs, such as rural toll or multiparty farm lines on carrier routes. It is costly to construct these pairs to *J3* standards with four pairs per arm. These are now erected on 12-wire arms and transposed to simple voice frequency patterns. These pairs do not degrade the performance of carrier pairs on the higher arms. To standardize on one type of arm for both carrier and voice frequency circuits it was decided in 1953 to use this 12-wire voice frequency arm as an 8-wire arm on 40-pole-per-mile routes by omitting the center pair on each side of the arm. This involves a pair spacing of 6 inches and an improvement of about 4 to 6 db in crosstalk. The attenuation is increased slightly.

Secondary Carrier Routes

Secondary routes are spaced at 28 poles per mile for reasons of economy. The use of the *J2* system is, however, not entirely satisfactory since fractional transposition sections must be spaced at 40 poles per mile. Consideration is at present being given to the use of the *LJ* transposition system (a variant of the *J3* system) at 28 poles per mile for all types of section. This involves a 9.14-mile full section. It is probable that such a route would accommodate a 12-channel system on at least half the carrier pairs for three or four repeater sections. This would meet the requirements for most secondary routes. The use of 6-inch spaced pairs on 28-pole-per-mile routes for carrier working is not favored on account of the possibility of wind contacts. The use of copper-steel wire on such routes would enable the 6-inch spaced arm to be used. The high attenuation of such wire at voice frequencies limits its use to short lengths unless a satisfactory and inexpensive solution to the problem of providing gain in physical circuits is forthcoming. The possibilities of the transistorized negative impedance repeater in this connection are being explored.

Extension of Frequency Range Beyond 143 Kc per Second

The formation of ice on open-wire conductors is a rare occurrence in South Africa, and then only in very restricted areas. Thus the possibility of using frequencies appreciably above the *SOJ* range appeared to be restricted by crosstalk considerations. Crosstalk could be reduced further only by shorter transposition intervals, since crosstalk coefficients and irregularity crosstalk had been reduced as far as practicable. It is not economical to reduce span lengths further; at 40 poles per mile most routes are already stronger than they need be. The use of suspended transpositions, while valuable for river crossings, does involve a number of construction and maintenance problems.

Measurements indicate that six pairs out of the eight on the first two arms of a *J3* 40-pole-per-mile route have satisfactory attenuation characteristics up to at least 250 kc per second, while the worst far-end crosstalk, Table IV, has deteriorated by not more than 20 db. The availability of a compact and

Table V. One-Year Analysis of 12-Channel Network Outage

Outage per 100 Channel Miles per Annum, 21 Hours 24 Minutes

Cause of Fault	Percentage of Fault Time

Faults which either came clear while being localized or where no faults were found	13.1

* Items such as condensers, rectifiers, etc., i.e., other than valves and fuses.

inexpensive compandor, giving a noise advantage of some 20 db or more, has thus made the application of another 12-channel group above the present *SOJ* systems on at least half the pairs a practical possibility. The top frequency of the new system is expected to be about 270 kc per second. The problems associated with such a project, e.g., method of frequency translation, pilot regulation, interaction crosstalk at repeaters, matching of entrance cables, etc., have been examined and it is proposed to install a number of systems in the near future. The same repeater sections will be employed since the compandor will be able to cope with the increased noise. It is proposed to employ these systems initially over not more than two or three repeater sections.

The Application of Carrier Systems to Early Types of Route

It is possible to operate one carrier system, even a 12-channel system, over almost any type of route, by suitably transposing the pair which will accommodate the carrier. The operation of more than one carrier system may require the insertion of a few poling transpositions or extensive retransposing.[8] It is also necessary to remove any sections of covered wire or cable interposed in the route.

Many of the earlier routes in South Africa embodied "revolved wires," i.e., a quad of four wires twisted or revolved making a complete twist in each four spans. Like all routes which employ special configurations to reduce mutual coupling, some pair combinations give good results while others are very poor. By a careful choice of pairs and the insertion of poling transpositions it is possible to operate several carrier systems over such routes. In one case 60 carrier channels were operated over such a route for 56 miles, although with somewhat relaxed crosstalk standards.[8] There is little doubt, however, that the flat carrier transposed route is superior to all other types of construction for carrier system operation.

Lead-in Arrangements

The *SOJ* carrier system with its extended frequency range introduces problems of matching between lead-in cables and the open wires not present with systems operating up to 30 kc per second.[7,8,15,16] The open-wire pairs are connected to the *SOJ* line filters by means of low-capacity star-quad cable having a characteristic impedance of 240 ohms. Variable load units are fitted to one or both ends of this cable and its impedance is built out to match the 575-ohm line, with a reflection coefficient of less than 5 per cent over the frequency range of 10 to 150 kc per second. In the frequency range of over 150 kc per second, it will be possible to permit a somewhat higher reflection coefficient, since the near-end crosstalk has not deteriorated as much as the far-end, the relative improvement being of the order of 10 db.

This arrangement is satisfactory for distances between the line and the equipment up to about 200 yards. For greater lengths it would be possible, but uneconomical, to use intermediate loading. In these cases the 12-channel line filters are divorced from the equipment and placed in a hut near the end of the route. The filters are connected to the terminal or repeater equipment by a paper-insulated star-quad 46-pair 16-gauge (40 pounds per mile) toll entrance cable. The high-pass side is brought in over an unloaded pair, giving a loss of 3.6 db per mile at 140 kc per second. The low-pass side is brought in over a pair loaded at intervals of 250 yards with 3-millihenry coils, giving a loss of about 1 db per mile at 30 kc per second. If the cable is short, the 3-millihenry loading may be dispensed with and autotransformers used at both ends of the pair for matching purposes. This latter arrangement does, however, introduce a considerable loss into the circuit and it is not favored for cables longer than about 500 yards.

In cases where only a limited number of 12-channel systems is proposed, and it is therefore possible to relax the impedance matching requirements, matching transformers covering the frequency range 0.5 to 150 kc per second are available. This transformer matches the open-wire line to the cable and eliminates the need for the filters at the terminal of the open-wire route.

Crosstalk in toll entrance cables is reduced to satisfactory values by suitably "doping" the joints on a basis of capacity unbalance and also by fitting crosstalk balancing condensers at one end of the cable.

Power Plant

Equipment installed up to about 1945 is operated from 24-volt and 130-volt d-c supplies. At most stations this is provided by one or more selenium rectifier units. The voltage regulation is achieved by tap-changing transformers controlled by what is essentially a moving-coil contact voltmeter. In the event of a failure of the public mains, or of the rectifier units themselves, the 24- and the 130-volt supplies are obtained from two d-c generators driven by an automatic-starting diesel engine. The break of about 10 seconds during which the engine is running up to speed is covered by very small batteries floated across the output of the rectifier units. On restoration of the mains supply the stand-by set recharges its starter battery.[6,8]

During the past 10 years, most carrier equipment has been operated from small power panels associated with each bay-side. Filaments are heated from a 6.3-volt a-c supply, while the plate voltage is 220 volts. This new arrangement has a great deal to recommend it,[1] though there are two important complications. In the first place, the mains voltage must be regulated to within 1 per cent and surges on the mains must be reduced as much as possible since they are applied directly to the equipment. Secondly, the problem of supplying a no-break stand-by power supply is not easily solved.

At less important stations, or where voice frequency telegraphs or broadcast carriers are not involved, automatic-starting Diesel-alternator sets are provided. In these cases there is a 5- or 10-second break in the supply on a mains failure. At all other stations a continuous a-c supply is provided by either of the following types of machine:

1. A synchronous motor running off the mains drives a large flywheel. On mains failure this motor supplies the load as an alternator driven by the flywheel and, at the same time, the flywheel starts the Diesel engine through a magnetic clutch.

2. The station is supplied from an induction-motor-alternator set running off the mains. This set drives a large flywheel. On mains failure the flywheel continues to supply the station by driving the set while the engine is brought up to near full speed before being magnetically coupled to the rest of the set.

There are several advantages in the second set described, e.g., mains voltage fluctuations tend to be smoothed out, the control circuits are simpler, and no synchronization of the machine with the restored mains supply is required.

The control equipment has proved to be the most vulnerable part of stand-by sets. It is essential that all relays and contactors be of the most reliable type and that all connections be as secure as possible. The sets should also be fitted with adequate and reliable alarms to cover a failure of any of the essential functions of the set.

Maintenance

Although maintenance standards on carrier systems have always been high, the tolerances of fault incidence and the stability requirements of toll circuits are even more stringent today, because of the following:

1. The automatization of the toll network in the form of operator dialing and in some measure customer dialing.[16]
2. The operation of circuits at or near zero loss equivalents, and the connection of several of these circuits in tandem.
3. The fact that a fault may affect a large number of channels.

EQUIPMENT PRACTICES

The effect of equipment practices on maintenance has already been mentioned. The more important points are:

1. Jack-in panels give ready access to components and wiring, and facilitate the repair and replacement of faulty panels.
2. The miniaturization of equipment should not be carried too far. The cost of floor space is low in relation to the equipment, and there are diminishing returns in miniaturization which may be absorbed by higher maintenance costs. It is, of course, also true that in some cases floor space is acutely limited, and in these cases very compact equipment may be essential.
3. There should be an adequate number of test points to facilitate the speedy location of faults. Where necessary it should be possible to make terminated, as opposed to level, measurements.
4. Controls, such as potentiometers, etc., should be concealed to prevent unwarranted or accidental operation.
5. The equipment should be reasonably dustproof.

RELIABILITY OF COMPONENTS

A system is no more reliable than its weakest component. Electrolytic condensers should in general be avoided. The voltage rating of condensers in decoupling circuits and in line filters must be generous. Wire-wound resistors should be used only for low-resistance values and where a high accuracy is necessary. Rectifiers in the form of metal rectifiers or germanium diodes are used extensively in modern circuitry and it is important that they should have stable characteristics. Catastrophic and emissive failures in thermionic tubes have been, and are still, receiving close and considerably successful investigation by manufacturers. Such special, or "trustworthy," tubes are of course more expensive than commercial tubes, but mean lives of between 3 and 10 years may be expected from them.

DEFECTIVE CONNECTIONS

As important as the components, are the connections between them. Careful control of soldering in both factory and field is essential. There is much to be said for soldering in tubes, particularly if they are reliable ones. Potentiometers employing contacts sliding over wire or studs, keys, jacks, blind sockets, riveted joints in links, or tags should be avoided. Flat-bladed links in spring sockets are superior to the round type. Contacts should always be of precious metal. The internal connections in such items as paper condensers, miniature rectifiers, etc., are possible weaknesses.

It is now the practice to subject all components and wiring after equipment installation to a vibration or percussion test.[17] Briefly, the method involves the sending of a test tone, of a suitable frequency and very low level, through the equipment to a demodulator followed by a high gain loudspeaker-amplifier. The disturbance of a bad connection modulates the test tone and produces a crackle from the loudspeaker. It is found that this method is very successful in revealing defective connections which appeared perfect under visual inspection. It is necessary to employ conscientious personnel for this type of testing.

TESTING EQUIPMENT AND MAINTENANCE AIDS

Terminal stations of any appreciable size and the more important repeater stations, are equipped with the following items of test equipment:

1. A continuously variable frequency oscillator covering the entire frequency range of the equipment, with the exception of the group translation stages in the *SOJ* systems. At larger stations there are additional oscillators, some covering the audio-frequency range only.
2. A nonfrequency selective transmission measuring set or sets to cover the entire frequency range of the equipment and capable of reading down to −40 dbm or in some cases—55 dbm. Most sets fall into one of the ranges, 30 cycles to 10 kc per second, 30 cycles to 150 kc, or 60 to 600 kc per second.
3. A multirange general-purpose 20,000-ohm-per-volt voltmeter with current and resistance scales.

At stations which have 3-channel terminals only, an 800-cps oscillator, together with a suitable level measuring set, is generally adequate. With some exceptions, no testing equipment is supplied for stations with single channel terminals only, since these are often unattended and small portable sets are carried by visiting maintenance personnel.

At the largest stations special items such as impedance bridges, psophometers, oscilloscopes, valve voltmeters, etc., are held. Harmonic analyzers for measuring the harmonic content of line amplifiers are also available at a number of stations but these have not proved convenient to use. Most equipment is mounted on suitable trolleys. This arrangement has proved most satisfactory since one set serves the maximum amount of equipment, the test leads are kept short, and the testing officer is in general conveniently near the equipment he is testing.

Experience has shown that it is important that station alarm systems be adequate, well maintained, and standardized throughout the country. The terminals and repeaters of important systems or routes are connected by a private telephone circuit, generally a physical line. On the longer systems a special circuit provides an immediate indication at both terminals of which repeater or repeater section has failed. The action of this circuit is quite independent of the faulty station or section since it is actuated by pilot alarms at adjacent repeaters. This device is of particular value in locating short breaks which have not been noticed by repeater attendants, and for calling out the correct attendant when faults occur during the night. It is important that the correct maintenance tools be available, particularly in regard to soldering equipment.

ROUTINE TESTING

Routine tests are not made as frequently as they once were. It is generally agreed that the value of such tests in preventing or anticipating faults has been over estimated. Channel equivalents at a single frequency are checked weekly in most systems, but it is probable that this period will be increased to a month or more in the case of short circuits. System levels at important points, such as the output of the line amplifiers, carrier supply levels, synchronization, etc., are generally checked at intervals of 2 or 3 months. The emission currents of tubes are no longer measured, with the exception of the line amplifiers on multichannel systems, in which case the measurements serve as a check on intermodulation products. The frequency response of channels is at present measured at intervals of 4, or in some cases 12, months. Consideration is being given to the elimination of this test. Annual overhauls are no longer made, since a system with adequate maintenance should never deteriorate to the extent which would make such an overhaul necessary. If the performance of the system as a whole, as indicated by the measurements mentioned, is satisfactory, there is little to be gained by measuring its individual parts.

FAULT PROCEDURE

The efficient clearance of faults depends on both the technical ability of the personnel and the manner in which they co-operate with each other. To achieve the latter it is necessary that the procedure for receiving and passing on information relating to faults and their clearance be specified in some detail.

In South Africa there is a main or master control station which is advised of important breakdowns and which if necessary issues instructions in regard to repairs, authorizes work on important circuits, and collates and analyzes fault data. Several subsidiary control stations function in a similar capacity for their respective areas, usually in regard to secondary routes, and act as clearing centers for information required by the main control station. The fact that certain stations are designated as fault control stations does not lessen the responsibility of personnel, irrespective of the status of their station, to exercise their initiative, and to act immediately a fault occurs.

While the quantity of equipment in service has increased considerably, the supply of skilled maintenance personnel has not kept pace with this increase. Fortunately modern equipment requires very little maintenance. On the other hand, this means that the maintenance officer gets very little practice in clearing faults. Centralized repair depots and points from which technical assistance may be obtained telephonically are of considerable value.

ANALYSIS OF FAULTS

Control stations receive fault details daily, and in some cases weekly. The information is coded so that the clerical work involved is reduced to a minimum. The information is then transcribed to fault cards on a system and on a circuit basis. The control stations examine the fault returns and the fault cards at frequent intervals and any unusual trends are followed up. On a short-term basis this follow-up generally involves a high fault incidence at or on a particular station, system, or circuit. On a long-term basis the analysis reveals weaknesses in particular types of equipment.

An analysis of the outage of the 12-channel network over a period of a year is given in Table V. The line faults predominate and the following shows the number of faults per 100 miles of open-wire circuit per annum, based on 96,500 miles of circuit including a considerable amount on secondary routes and some on old routes:

Broken wires and binders	1.61
Protector faults	1.47
Faults due to any external objects except trees	0.96
Tree faults	0.53
Slack wires	0.38
Broken insulators	0.38
Wires cut by lightning	0.35
Faults due to workmen	0.14
Faults due to power contacts or surges	0.03
All other faults	0.96
Total	6.81

The contribution of line faults has been reduced very considerably by the provision of stand-by or reserve physical circuits for 12-channel systems. Power plant failures are relatively few in number but their contribution is high since one fault often affects a large number of circuits. A considerable number of the short breaks which occur appear to be due to unauthorized interference by maintenance staff, and it is important that stringent measures to prevent this be applied.

Protection from Lightning Damage and Interference

A considerable amount of lightning is experienced in South Africa: in several parts there are over 70 thunderstorm days per year.[18]

On a long open-wire line, such as a toll line, the crest surge current which occurs as a result of a near-by ground stroke rarely exceeds 200 amperes. The high currents associated with a high ground resistivity do not arise as they do on short customer lines. The current through the terminal protectors is in general of an oscillatory nature, partly because of successive reflections from the ends of the line which may increase the duration of the surge to about 1 to 5 milliseconds.

Air-gap metal-electrode protectors sealed in polyvinyl-chloride give very satisfactory service on toll lines. Gas protectors are not used in lightning areas because when damaged by lightning they give no indication of failure.

Toll protection at the end of an open-wire pair thus consists of two metal-electrode protectors with a drainage or equalizing coil. This latter coil is very effective in reducing the transverse voltage resulting from protector operation. No heat-coils or fuses are employed. It is important to bond the protector earth to the earth of the equipment, e.g., line filters, and also to the sheath of the lead-in cable. In high resistivity soil, where it may be difficult to obtain a low resistance earth connection, a horizontal buried wire provides the most economical solution.[19] In spite of the high lightning incidence and considerable amount of equipment installed in South Africa, the damage which occurs is negligible.

Apart from the effects of lightning discharges, protectors may operate due to changes in the electric gradient near the ground during periods of thunderstorm activity. In these cases the currents which pass through the protectors are less than a few milliamperes. The protector operation does, however, cause noise and this effect may be overcome by earthing the centerpoint of the line transformer, or by employing a drainage element such as silicon-carbide.

The effects of lightning on carrier telephone and voice frequency telegraph systems have been studied in some detail.[18] Briefly, the nature of the transients at the various points are determined by the filter characteristics. The frequency of oscillation is at the mid-band of a band-pass filter and at the cutoff frequency of a low-pass filter. The duration of the transient is a function of the bandwidth: the narrower the bandwidth the longer the duration. There is no appreciable lengthening of the transient until the output of the low-pass filter following the channel demodulator is reached. The important lengthening process occurs in the receiving telegraph filter, where the duration is always about 20 milliseconds for a 120-cycle spaced telegraph system. The peak voltage of the transient tends to increase as the gain of the terminal is increased.

It is found that amplitude-modulated voice frequency teletype circuits can be operated over open-wire carrier telephone channels with a negligible number of mutilations even under severe thunderstorm conditions, provided drainage (equalizing) coils are used, and provided that the system line levels are sufficiently high. The gain-time characteristics of the telegraph detector are also of importance. Operation over 12-channel systems is superior to operation over 3-channel systems.

Frequency-modulated telegraph systems are superior to amplitude-modulated systems as far as lightning mutilations are concerned but until their cost can be made comparable to that of amplitude-modulated systems, their use on high-quality carrier telephone channels is not justified.

Regulator Curves and Transient Currents of Double-Way and Double-Wye Rectifiers

L. E. JENSEN
ASSOCIATE MEMBER AIEE

C. E. RETTIG
ASSOCIATE MEMBER AIEE

CALCULATION of instantaneous and sustained current resulting from d-c faults on a power rectifier is extremely cumbersome. Certain idealized cases have been treated analytically, an important factor in establishing and understanding the circuit action. The analytical treatment also provides a necessary check on results obtained by other methods.

One effective way to reduce the amount of cumbersome calculation in such problems is to set up a model or miniature of the full-scale equipment which duplicates known conditions. This model or miniature can then be used to extend investigations through a great variety of circuit conditions with a considerable saving of time and effort over purely analytical treatment.

An extensive study of typical circuit conditions has been made with the transient network analyzer.[1] This study has resulted in a fairly complete coverage of regulation curves and current transients during d-c faults for most power rectifier operating conditions; and a simplified method of obtaining regulation and transient currents for typical power rectifiers.

Rectifier Circuits

The 6-phase double-way and 6-phase double-wye circuits used in the miniature study are shown in Fig. 1. The equivalence between double-way and double-wye rectifiers has been developed analytically in previous papers[2,3] and was verified by the use of the transient analyzer. Most of the data in this paper were taken with the double-way circuit.

Transient Analyzer Components

Germanium cells with the characteristics shown in Fig. 2 were used as the rectifying devices. Voltage and impedance magnitudes were chosen to make the voltage drop of the germanium cells negligible. The "arc-drop" of the cells was less than 0.3 per cent (%) of E_{d0} for the double-way circuit. The reactance elements had resistance-reactance (R/X) ratios in the order of 0.025. Thus,

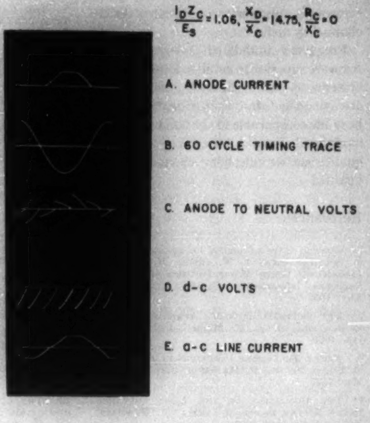

Fig. 4 (right). Change-over between second and third modes, inductive load

idealized conditions could be very closely approximated in checking against analytical work.

List of Symbols

I_d=steady-state d-c current, average amperes
i_d=instantaneous value of d-c current
i_1, i_2, etc.=instantaneous value of current in anode 1, anode 2, etc.
i_a, i_b, i_c=instantaneous a-c line currents
E_d=d-c terminal voltage, average value
E_{d0}=d-c voltage at no-load, average value
E_s=a-c line to neutral voltage at no-load, rms value
$Z_1=\sqrt{R_1^2+X_1^2}$=a-c circuit impedance referred to E_s voltage base
$X_1=2\pi fL_1$=a-c circuit reactance
f=a-c power system frequency, cycles per second
$Z_2=\sqrt{R_2^2+X_2^2}$=anode circuit impedance
$Z_c=\sqrt{(R_1+R_2)^2+(X_1+X_2)^2}$ = line-to-neutral commutating impedance
$Z_d=\sqrt{R_d^2+X_d^2}$–d-c circuit impedance external to rectifier

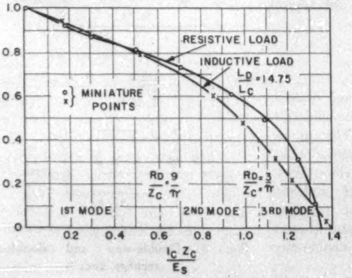

Fig. 3 (left). Comparison of miniature and theoretical regulation curve with commutating inductance only

Extended Regulation Curves

Regulation curves have been calculated by previous authors for the cases of highly inductive loads and of resistive loads, the commutating impedance in each case being purely reactive.[2–4] These curves are replotted in Fig. 3 along with points obtained from the miniature study showing the very close correspondence between theoretical and miniature curves. Oscillograms of voltages and currents, Figs. 4, 5 and 6, were taken of the points of change in mode of operation. These oscillograms also show excellent agreement with the theoretical wave forms.

Since rectifier resistance is omitted in these two idealized cases, the results are pessimistic. The curves indicate higher values of fault current than would be obtained in an actual rectifier. For example, calculations of regulation at rated load include a resistance loss component E_r as well as a reactance component E_x. The value of E_r is practically never less than one-third of E_x and in many cases it may be as high as two-thirds of E_x.

Figs. 7 through 10 show regulation curves for various values of R_c/X_c in comparison with the idealized curves. These curves were taken with both inductive and resistive loads. It can be seen that commutating resistance R_c reduces the difference between the cases of highly inductive and resistive loads. Also, the effect of R_c is of considerable importance. The range of the R_c/X_c ratio for practically all rectifier applications is between 0.11 and 0.43, shown in Table I of reference 5. This range is covered in Figs. 7 through 10.

For maximum usefulness it is desirable to have the regulation curve represented as simply as possible commensurate with desired accuracy. Fig. 11 shows straight-line approximations for the conditions covered in Figs. 7 through 10. The accuracy of this representation is within +9.0% or −2.5%. That is, a calculated value may be 2.5% lower than the actual current when E_d/E_{d0} is 0.3 and the R_c/X_c ratio is 0.12 with resistive load. The calculated value may be 9.0% higher than the actual current when $E_d/E_{d0}=0.55$ and the R_c/X_c ratio is 0.12 with inductive load. As the R_c/X_c ratio increases, the representation becomes more accurate.

Examination of arc-drop oscillograms taken under fault conditions indicate that the arc-drop is most accurately represented as a battery voltage. Since this voltage has no effect upon commutation, it may be considered as a single

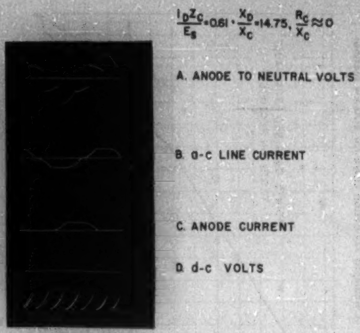

Fig. 5 (left). Change-over between first and second modes, inductive load

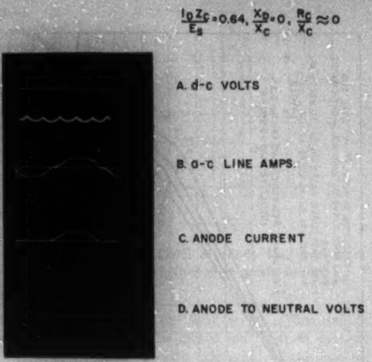

Fig. 6 (right). Change-over between first and second modes, resistive load

battery in the d-c bus. Typical values are indicated in Fig. 11. More precise values for particular applications depend upon the tubes or tanks used and the design value of short-circuit current. After obtaining a theoretical short-circuit current value from Fig. 11 a value of arc-drop may be selected from Figs. 8 or 9 of reference 6. This arc drop for the theoretical bolted fault conditions determines the maximum value of the straight-line approximation.

An approximate regulation curve for a particular application may be derived from Fig. 11. The intersection of arc-drop curve and appropriate regulation curve determines the value of bolted short-circuit current. The voltage at the break in the approximate regulation curve is reduced by the arc-drop at that current and the open-circuit voltage is reduced by the no-load arc-drop.

An example may clarify the procedure. Circuit constants of a 200-kw 300-volt sealed-ignitron rectifier, 6-phase double-wye connection will be used. Actual fault tests made on this rectifier will then serve as a check on the accuracy of the method. The circuit constants are as follows (commutating impedance shown in Table I).

Table I. Commutating Impedance

	X_c, Ohms	R_c, Ohms
Supply lines	0.026	0.0032
Rectifier transformer	0.060	0.0154
Anode leads	0.003	0.0030
	0.089	0.0216

$$Z_c=\sqrt{R_c^2+X_c^2}=0.0916 \text{ ohm per phase}$$

$$\frac{R_c}{X_c}=0.243$$

Transformer voltage is

$E_s=297$ volts line-to-neutral

Theoretical no-load voltage is

$E_{d0}=1.17\ E_s=348$ volts

Theoretical bolted fault current per wye is

$$I_c=1.41\times\frac{E_s}{Z_c}=1.41\times\frac{297}{0.0916}=4{,}570 \text{ amperes}$$

Arc drop is, at no load

$$E_a=15 \text{ volts}, \frac{E_a}{E_{d0}}=\frac{15}{348}=0.043$$

and at 4,570 amperes

$$E_a=20 \text{ volts } \frac{E_a}{E_{d0}}=\frac{20}{348}=0.057$$

D-c impedance is shown in Table II.

Table II. D-C Impedance

	X_d, Ohms at 60 Cycles	R_d, Ohms
Interphase transformer	0.0018	0.0008
Lines to short-circuiting breaker	0.0300	0.0025
	0.0318	0.0033

The effect of the interphase transformer resistance is small but may be accounted for by adding its per-unit voltage drop at the theoretical bolted fault current to the arc drop. Thus

$$\frac{E_a'}{E_{d0}}=\frac{E_a}{E_{d0}}+\frac{2\times1.41E_s}{Z_c}\times\frac{R_d}{E_{d0}}=0.057+$$
$$9{,}140\times\frac{0.0008}{348}=0.057+0.021=0.078$$

The effect of interphase transformer inductance and bus inductance with this R_c/X_c ratio is small, and will be neglected in this example.

The modified arc-drop line may be constructed on Fig. 11 by joining the two points $(I_cZ_c/E_s=0)$, $(E_a/E_{d0}=0.043)$ and $(I_cZ_c/E_s=1.41)$, $(E_a/E_{d0}=0.078)$. The intersection of this line and the regulation curve for $R_c/X_c=0.243$ (interpolated midway between the curves for $R_c/X_c=0.21$ and $R_c/X_c=0.30$) determines the bolted fault current. In this case $I_cZ_c/E_s=1.33$. Therefore the sustained bolted fault current is

$$I_d=2\times1.33\times\frac{E_s}{Z_c}=2\times1.33\times\frac{297}{0.0916}=8{,}620 \text{ amperes}$$

The no-load voltage is

$E_{d0}-E_a=348-15=333$ volts

The point at which the regulation curve breaks, located by the co-ordinates, is

$$\frac{I_cZ_c}{E_s}=0.93$$

$$\frac{E_d}{E_{d0}}=0.48-0.07=0.41$$

or

$$I_d=2\times0.93\times\frac{E_s}{Z_c}=2\times0.93\times3{,}240=6{,}030 \text{ amperes}$$

$E_d=0.41\times348=143$ volts

The regulation curve determined by these points is shown in Fig. 12. Points obtained by oscillograph measurements of faults on this equipment are also shown in Fig. 12. Observation of this figure shows that the accuracy obtainable with these curves is as good as the precision in oscillographic measurement.

In some cases it may also be desirable to include the effects of anode circuit inductance. Regulation curves including the effect of anode circuit inductance are

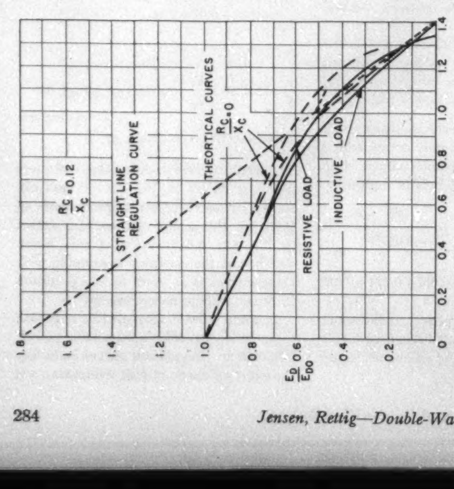

Fig. 7 (left). Regulation curve including commutating resistance $R_c/X_c=0.12$

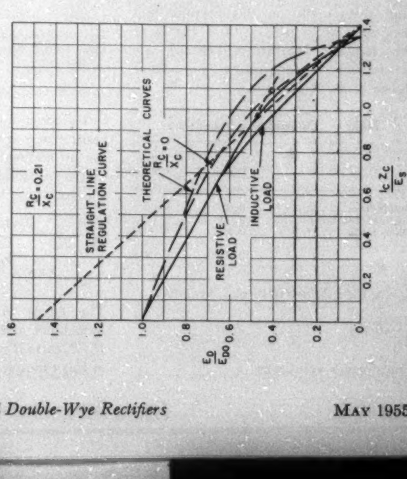

Fig. 8 (lower left). Regulation curve including commutating resistance $R_c/X_c=0.21$

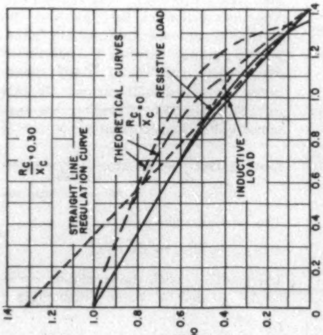

Fig. 9 (above). Regulation curve including commutating resistance $R_c/X_c=0.30$

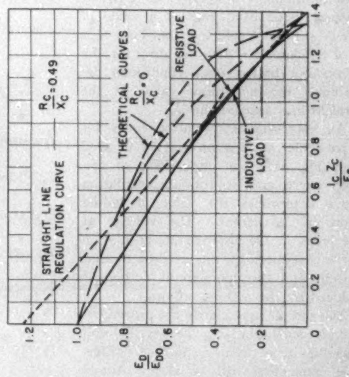

Fig. 10 (below left). Regulation curve including commutating resistance $R_c/X_c=0.49$

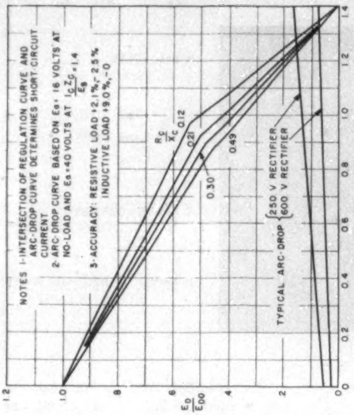

Fig. 11 (above). Straight-line regulation curves

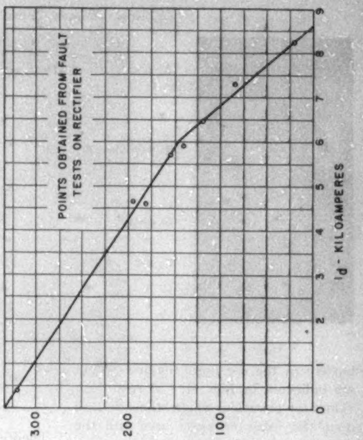

Fig. 12 (below). Calculated regulation curve for 200-kw rectifier

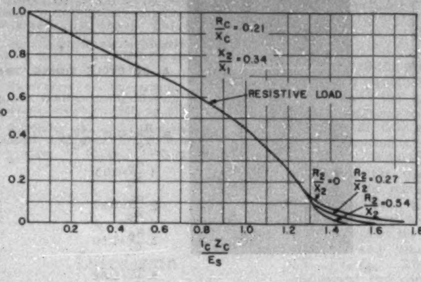

Fig. 13 (left). Effect of anode lead impedance

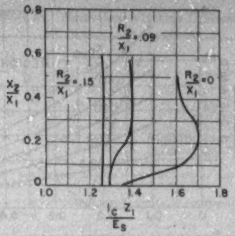

Fig. 14. Effect of anode lead impedance on bolted short-circuit current

shown in Fig. 13 for the case of $X_2/X_1=$ 0.34. The inductance added in series with each rectifying element could represent secondary leakage plus lead inductance. For the majority of the regulation curves the reactance X_2 adds directly to X_1. However, for the bolted short-circuit condition X_2 has the effect of increasing the steady-state fault current, as is shown in Figs. 13 and 14.[6]

The explanation of this phenomenon is given in reference 6. Inductance in series with each anode extends the time of conduction of each anode beyond 180 degrees at the bolted-fault condition, thereby resulting in higher d-c short-circuit current. Practical values of R_2/X_2 are not usually lower than 0.22. The combined effect of arc-drop and R_2/X_2 ratio is such that the actual current will not exceed the straight-line approximation.

Transient Fault Currents

When a short circuit occurs on a d-c circuit of a rectifier, a peak current greater than the steady-state fault current may or may not occur, depending on the relative values of the circuit impedances. The miniature circuits of Fig. 1 were also used to study transient behavior of the short-circuit current as a function of circuit impedances. Switch S_1 of Fig. 1 is a rotating switch driven by a synchronous motor. Another switch driven by the same synchronous motor was used to trigger the sweep circuit of the oscilloscope. Thus, switch S_1 could be closed and opened, in synchronism with triggering of the oscilloscope, several times a second so that the transient current trace appeared to stand still on the oscilloscope screen. Pictures of the traces were taken with a special camera when desired.

The wave shape of the transient currents are shown in Fig. 15. The peak current is limited by either resistance or reactance in the fault, or by both, as shown in Fig. 16.

For the case of a bolted fault or a resistance fault the current during the transient interval is made up of two components. One is the sustained current, the other is an a-c component of power system frequency which decays in

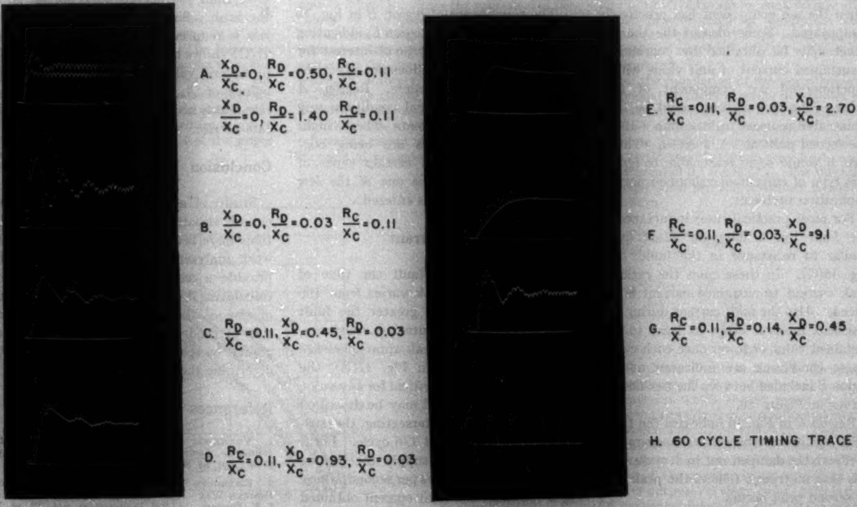

Fig. 15. Oscillograms of typical transient currents with impedance in fault

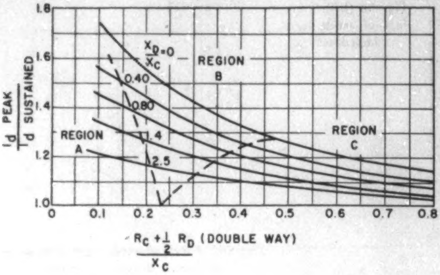

Fig. 16 (above). Effect of impedances on peak current

an exponential manner. The larger the resistance to reactance ratio, the more rapidly the exponential decays. See Fig. 15(A) and (B). Since the a-c component must be equal to the sustained component at the time the fault is applied, the first crest of current occurs approximately 1/2 cycle after the fault application. Considering the extreme condition where $R_c/X_c=0.12$ with bolted fault, the peak current is 1.68 times the sustained current. Except for the stresses developed in the rectifier transformer, the principal interest in this peak current is in the thermal effects. The influence on d-c circuit breakers would be thermal. The breakers do not interrupt until the ensuing trough of current is reached at the end of 1 cycle (for high speed breakers) or until 2 or more cycles have elapsed (for medium- and low-speed breakers) when the a-c component has practically disappeared. Some idea of the thermal effect may be obtained by considering a sustained current of unit value with a superimposed a-c component of 0.68 value. The rms current would be 1.21. This value reduces to less than 1.10 on the second peak at 1 1/2 cycles. Therefore, it would seem reasonable to ignore this type of current overshoot in normal application problems.

For most practical cases inductance in the fault has a damping effect quite similar to resistance in the fault. See Fig. 15(G). In these cases the ratio of peak current to sustained current is reduced. Also the fault current during the transient interval drops at least to the sustained value or lower once each cycle. These conditions are indicated as the region *B* included between the two dotted curves in Figure 16.

Region *C* in Fig. 16 indicates the transient conditions where a peak occurs but is effectively damped out in 1 cycle. In this case no trough follows the peak and no second peak occurs.

Region *A* in Fig. 16 indicates the transient conditions where the d-c circuit has a long enough time constant that the d-c fault current does not follow the a-c currents into the trough. The dividing line was chosen for the condition wherein the current troughs following each peak were equal to or greater than the sustained value.

The significance of region *B* in Fig. 16 has been discussed. Region *C*, indicating a 1/2-cycle peak, may be of interest for the thermal effect but does not affect the interrupting requirements. Region *A* may affect both thermal conditions and interrupting requirements where high-speed circuit breakers are being considered. Flashover of certain types of d-c machines would be one of the few cases where region *A* is entered.

Rate of Rise of Current

With a resistance fault the time of occurrence of the peak varies from 180 to 120 degrees. The greater the fault resistance and commutating resistance, the more nearly the peak approaches 120 degrees. As shown in Fig. 17(B), the initial rate of rise is identical for any value of fault resistance, and may be described as a straight line intersecting the sustained fault current at 1/6 cycle. For a 60-cycles per second supply the rate of rise is 360 × I_d amperes per second, where I_d is the sustained fault current obtained from Fig. 11.

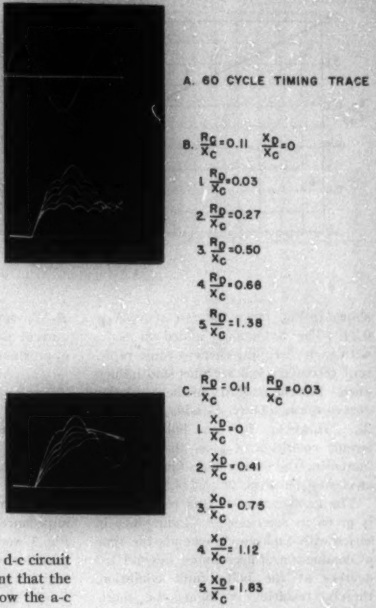

Fig. 17 (right). Oscillograms of transient currents with peaks with inductance in fault

With both resistance and inductance in the fault, the peak current may occur later than 180 degrees after initiation of the fault. Similarily, the initial rate of rise is reduced by the inductance. Fig. 17(C) shows the magnitude of this effect for several values of X_d/X_c. For larger values of X_d/X_c the ratio E_{d0}/L_d is a reasonably accurate measure of the initial rate of rise.

Conclusion

Study of a great number of rectifier circuit variations under d-c fault conditions have been made on a transient network analyzer. The results of this study provide a reasonably simple method of calculating d-c fault currents and the rate of rise of these currents. Accuracy of this method is commensurate with the ability to specify the impedances which determine these currents.

◆

Discussion

I. K. Dortort (I-T-E Circuit Breaker Company, Philadelphia, Pa.): This paper provides another excellent experimental check on the theoretical work of previous authors. In addition, it offers a practical means of attacking the problem of real rectifiers under transient conditions. Using the data presented, I have rechecked the approximate method which is given in Fig. 1 of reference 4 of the paper for the case of noninductive loads.

The derived regulation curves given in Fig. 1 of that paper are essentially correct except for an error in the resistance line. In equation 7 of that paper it was assumed that the copper losses of the rectifier transformer and anode cables would increase as the square of the direct current I_d. Because of the change of wave shape of the anode currents, which become sinusoidal as we approach short circuit, the copper losses increase at a lesser rate and the equivalent voltage drop increases less rapidly than the direct current. In terms of the load-loss P_r caused by anode currents of normal wave shape flowing through the total commutating resistance R_c at rated direct current I_{dn}, sinusoidal anode currents adding up to the same direct current would result in a load loss of $\pi^2 P_r/12 = 0.822\ P_r$. The losses in the d-c circuits, interphase-transformer, and arc, are not materially affected by the anode current wave shape. Assuming, for the sake of simplicity, that the anode currents are sinusoidal over the entire range of load, equation 7 of reference 4 of the paper becomes

$$E_r = E_{ao} + mR_a I_d + \frac{0.822 P_{r(ac)} I_d}{I_{dn}^2} + \frac{P_{r(dc)} I_d}{I_{dn}^2}$$

In Fig. 18 the first curve represents the theoretical regulation curve of an idealized rectifier and the straight resistance lines (approximations) are based on R_c/X_c ratios of 0.12, 0.21, 0.30 and 0.49 as used in the four corresponding tests of the paper under discussion. Subtracting these resistance lines from the theoretical no-loss curve results in the regulation curves for these four conditions. Superimposed on them are heavy curves transcribed from the test curves given by the authors in Figs. 7, 8, 9, and 10, and transformed to the base $(X_{cpu})(I_d/I_{dn})$. The areas between the theoretical and corresponding test curves have been cross-hatched and it can be seen that the difference is never greater than $2^1/_2\%$ in the vicinity of short circuit.

The agreement for cases $R_c/X_c = 0.12$ and 0.21 is almost perfect. The larger discrepancies in the curves for $R_c/X_c = 0.30$ and 0.49 have not been accounted for. Considering the simplifying assumptions used to derive the theoretical curves and the poor resolution of the published test curves used for comparison, the over-all verification is almost startling.

The results of the tests made by the authors on the 200-kw test rectifier were handled the same way with excellent results. The resistance line and derived regulation curve are shown dotted on the accompanying illustration.

The points depicted by small circles are taken from the test points of Fig. 12 of the paper. It will be noted that the value 1.0 for S gives a bolted short-circuit current of 8,200 amperes, whereas the approximate method used by the authors comes to 8,620 amperes. In Fig. 12 the last test point shown occurs at 8,200 amperes and approximately 20 volts. Since the resistance of the cables to the short-circuiting breaker is 0.0025 ohm it seems that the voltage readings were taken at the rectifier terminals and that the actual short-circuit current was 8,200 amperes.

From the circuit constants given by the authors for the 200-kw test set, it appears that this is the same equipment described in reference 5 except for minor changes and the increase of secondary voltage from 283 to 297 volts. The actual short-circuit current obtained in the earlier tests was 7,700 amperes. Correcting the 8,200 amperes predicted by the theoretical curve by the ratio of secondary voltages, the method I have proposed yields a bolted short-circuit current of 7,800 amperes.

Considering the inaccuracies contained in the curves of Fig. 11, it seems a pity the authors did not incorporate average arc-drop characteristics in the curves, instead of requiring a separate operation to obtain equivalent constants. Applying the two arc-drop lines for 250- and 600-volt rectifiers to Fig. 18, the maximum difference in bolted short-circuit current is only $4^1/_2\%$ when tested on the least favorable curve $R_c/X_c = 0.49$.

The deviation between rectifiers in any one class would of course be much smaller, and a family of curves for each voltage class would provide accurate equivalent constants at a glance. To the same end, use of a rational interval for R_c/X_c, will facilitate interpolation.

For the calculation of the contribution of individual rectifiers to faults in complex d-c systems, a table of equivalent machine constants may be even more useful. As an example, Table III was constructed for 300-volt rectifiers with noninductive loads, using an interval of 0.1 for R_c/X_c. For this table the equivalent per-unit resistance is derived as follows

$$\mathcal{R} = \frac{\Delta E_d}{\Delta I_d} = \frac{\Delta E_{dpu}}{\Delta S} X_{cpu} \frac{E_{do}}{I_{dn}}$$

$$\mathcal{R}_{pu} = \frac{\Delta E_{dpu}}{\Delta S} = \frac{\mathcal{R}}{X_{cpu}\dfrac{E_{do}}{I_{dn}}}$$

Table III. Equivalent Machine Constants

R_c/X_c	$\mathcal{E}_{1pu}$	$\mathcal{R}_{1pu}$	S_1	$\mathcal{E}_{2pu}$	$\mathcal{R}_{2pu}$	S_2
0	0.95	0.50	0.82	2.16	1.97	1.10
0.1	0.95	0.58	0.80	1.89	1.74	1.08
0.2	0.95	0.67	0.79	1.67	1.57	1.05
0.3	0.95	0.75	0.77	1.49	1.45	1.02
0.4	0.95	0.84	0.74	1.35	1.38	0.98
0.5	0.95	0.93	0.70	1.25	1.35	0.93

$\mathcal{E}_{1pu}$ = equivalent machine per-unit voltage for first phase

$\mathcal{R}_{1pu}$ = equivalent internal per-unit resistance for first phase

$S_1 = X_{cpu}\dfrac{I_d}{I_{dn}}$ at intersection of first and second phase

$\mathcal{E}_{2pu}$ = equivalent machine per-unit voltage for second phase (near short-circuit)

$\mathcal{R}_{2pu}$ = equivalent internal per-unit resistance near short circuit

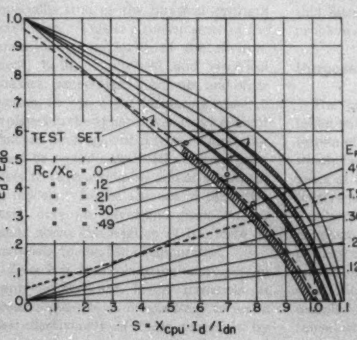

Fig. 18. Comparison of theoretical and test curves

W. R. Crites (General Electric Company, Schenectady, N. Y.): This paper presents information which should prove of great value in the analysis of current transients on d-c systems involving rectifiers. The regulation curves permit the determination of an equivalent resistance which can be used to represent the rectifier in an equivalent circuit for purposes of short-circuit calculation. Of particular interest is Fig. 16 concerning the possible occurrence of a peak on the d-c fault current and the magnitude of that peak.

A knowledge of the peak current is important in determining the adequacy of circuit breakers, busses and other system components. In this respect, the authors have stated that high-, medium-, and low-speed circuit breakers will not interrupt the current until after the peak value has been passed. This is true of the medium and slow-speed circuit breakers; however, there are high-speed breakers available which may operate in approximately one-half cycle and which would in that event be required to interrupt the peak current. The slower circuit breakers must pass the peak current and are therefore subjected to the forces associated with it even though they may not be required to interrupt it. Busses and other circuit elements through which the current passes will also be subjected to the forces of the peak current. The effect of these forces on the system components depends on the physical construction of the components, that is, such factors as mechanical strength and resonant frequencies.

In consideration of these factors, it appears that the authors' conclusion, "Therefore, it would seem reasonable to ignore this type of current overshoot in normal application problems," requires fuller explanation than is given in the paper.

L. E. Jensen and C. E. Rettig: The excellent agreement with the analysis by Mr. Dortort helps to show the effectiveness and accuracy of the miniature circuit used in this study, thus demonstrating the usefulness of the transient analyzer.

The approximate regulation curves of Fig. 11 were intended to show how assumptions could be made to simplify the calculation of short-circuit currents. Arc-drop effects could be included in the regulation curves so that fault currents could be read directly but it was felt that it would be better to keep the arc drop separate so that the reader could see at a glance what approximations were being made. Further simplification may be desired in some cases while in others greater accuracy may be desired. All of the curves for the various conditions have been included in the paper so that the reader may obtain the degree of precision which is desired for his particular needs.

The authors are aware that some high-speed breakers may interrupt near the time of occurrence of the transient peak of current. It was not the intention to imply that this overshoot should always be ignored. Later in the paper, information was included so that the reader could reach the degree of accuracy desired. Thus the curves of Fig. 16 which were of particular interest to Mr. Crites were included so they could be used for just such conditions as he suggests.

Significant Factors in Thermal Aging Tests on Flexible Sheet Insulation

T. W. DAKIN

H. M. PHILOFSKY
ASSOCIATE MEMBER AIEE

W. C. DIVENS
STUDENT MEMBER AIEE

THE revision of the present temperature classification of insulating materials as in AIEE Standard No. *1*[1] seems increasingly necessary to accommodate insulation application practice and apparatus temperatures to the higher temperature at which some of the newer synthetic materials seem to be safely operable. It has been the goal of the Working Group on the Evaluation of the Thermal Stability of Insulating Materials which was set up in the Basic Science Subcommittee on Dielectrics to develop acceptable standard methods of evaluating the thermal stability of insulating materials. Such methods should put any revision of the present standards onto a rational and conservative basis.

An acceptable method of evaluation of the life of an insulating material should have a proven relation to the operation of this insulation in apparatus. An attempt should be made to avoid arbitrary criteria of life end points. It is desirable to have a clear-cut general rule, but this should not be at the sacrifice of correlation with practical experience and the required function of the insulation. For example, it is not logical to rule the insulation dead when it has lost 50 per cent of its initial dielectric strength if the application required only 5 per cent of it.

In many cases the engineers who design apparatus and apply insulation cannot give a clear-cut answer in numbers to the question of what properties are required of the insulation they use. This is especially true of the physical strength properties. This is a consequence of the tremendous complexity of the environment, both of physical and electrical stresses, temperature gradients, and other factors, in which the insulating material is placed in the apparatus. It is apparent that the development of tests on materials must be co-ordinated with at least some tests to destruction on actual apparatus or models. In the absence of the latter tests, only an intelligent guess can be made about the relation of life tests on materials to the life of apparatus.

Since it is desirable to make progress in applying new and better materials as soon as possible, it is necessary to prove the effectiveness of these materials by accelerated tests. The most reasonable way of accelerating the degradation of insulation to determine its life, and, at the same time, to obtain information about its expected life under unaccelerated conditions, is to raise the temperature. It had already been pointed out[2] that chemical reaction rate principles apply to insulation aging and that these principles are used to extrapolate the results of short-time tests at high temperatures to longer times at more normal temperatures. This extrapolation is made by using the relation between temperature and life at some arbitrary end point, i.e.

$$\log (\text{life}) = k_1 + k_2/T$$

where T is the absolute temperature, and k_1 and k_2 are constants characteristic of the material being tested and the test conditions. The accuracy and applicability of this relation has been shown in a good many tests. However, to sound a note of caution, there are some situations which are too complex for it to fit. It is best that it be checked in each new situation by determining the linearity of a plot of log (life) versus $1/T$ by measuring the life a a series of a least three different temperatures in accelerated tests.

It should be thoroughly understood, however, that an accurate extrapolation from an accelerated high-temperature test does not of itself give a correct and useful result unless the accelerated test accurately represents the aging-to-failure conditions in the application. Satisfying this latter condition is the crux of the problem.

Purpose of Present Investigation

The present investigation was undertaken with the object of evaluating a life test method for varnished glass cloth which had been in use for a number of years at the Westinghouse Research Laboratories. The test was very simple: a 4-mil standard weave glass cloth was impregnated by a motor-controlled dipping process with the varnish baked, given a second dip, and finally cured. The initial dielectric strength of a representative sample of the varnished sheet was obtained and aged in an oven at a constant high temperature while held flat between layers of glass cloth. It was removed periodically from the oven to be proof-tested at room temperature at 50 per cent of its original dielectric strength. A 2-inch electrode was applied momentarily in succession to a number of different spots on the sheet so that a sizeable fraction of the total area was tested each time. Several 6- by 6-inch sheets were usually tested in parallel. The end point was arbitrarily set when half the spots tested failed.

The 50-per-cent dielectric strength criterion of end point has been used extensively;[3-6] sheet or tape insulation directly applied to conductors were tested and, in most cases, subsequently dipped in varnish. Such tests are more nearly representative of the application, but they involve variable factors peculiar to the manner of wrapping or taping or varnish treating which affect the observed life but may not be characteristics of the original tape or sheet material if it were applied to the conductor differently. It is likely that both types of tests should be done.

A critical analysis of this life test method seemed in order, to determine the real value of such a test for the purpose of measuring the operating temperature limits of insulating materials. It was felt that this analysis would spotlight a number of points of general significance to the whole program of insulation material life testing.

Such an analysis can be begun by asking several salient questions: what was really being tested—the relative life of the varnish to some other varnish or the absolute life? or a much more restricted thing—only the life of this particular composite insulation to a particular level of dielectric strength when aged in a particular way? The possible correlation of this test with the expected life of similar insulation in apparatus, and the correlation of this with other property tests should be looked into. The failure mechanism and criterion of failure as well as a number of factors associated with the test procedure need to be examined for their effect on the result.

Factors Affecting Life Test Results

It was known almost from the initial use of the test that varnishes which were

Paper 55-37, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing November 17, 1954.

T. W. DAKIN, H. M. PHILOFSKY, and W. C. DIVENS are with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

believed from general experience and other physical tests to be more thermally stable usually showed longer life on the test. For example, the silicone varnishes showed vastly longer life at comparable temperatures than the conventional organic varnishes. In fact, it proved to be impractical to test most organic varnishes at the same temperature as silicone varnishes, their apparent lives on the test being so vastly different. Thus, the value of the test in the laboratory seemed to be chiefly in its ability to give a reproducible and positive differentiation between different varnishes. This is illustrated in Fig. 1, where the lives of two different organic varnishes and two different silicone varnishes are graphed as a function of temperature.

These data in Fig. 1 indicate the differences in life of organic materials which, in the present classification system, would be rated exactly the same. It is indicated that insulation incorporating varnish *A* could be operated about 20 degrees higher than varnish *B* with a comparable life. Similarly, more than a 30 degree higher operating temperature would be possible with the better silicone varnish *A* over the silicone varnish *B*. Both of these are now restricted to 180-degree (Class H) temperatures. Tests such as these indicate that 180 degrees is too high a temperature for some poorer silicones but much too low for some of the superior silicones. Accelerated test data, shown in Fig. 1, can be used by extrapolation to predict the life at lower operating temperatures.

In discussing the variation of the life test results with different varnishes, the mechanism of failure should be considered. The test procedure measures the time for the dielectric strength to diminish to a certain level. The dielectric strength of varnished glass is largely caused by the varnish, the glass serving only as a skeleton spacer. The dielectric strength may decrease in the aging process by several means: loss in thickness of the varnish layer by evaporation (of decomposition products or initial low molecular weight constituents), by cracking of the varnish, or by a change in the chemical composition of the varnish which changes its dielectric strength for the same thickness. The last named effect might, on theoretical grounds, even be expected to increase the resin dielectric strength, unless the resin power factor is increased abnormally. Experience in examining the test specimens indicates that cracking is usually the most important factor in decreasing the dielectric strength, although evaporation can be quite an appreciable factor with some organic resins. Thus, the test method measures the time for an arbitrary extent of cracking to occur together with, in some cases, an amount of evaporation which collectively reduce the effective thickness of the insulation by half. The cracking results from a decrease in flexibility and shrinkage of the resin, probably caused by polymer cross-linking reactions. This makes the resin incapable of accommodating itself without rupture to the stresses imposed by its differential expansion and contraction in the glass cloth framework.

It should be recognized that the test itself sets several arbitrary conditions which may not be representative of the varnished glass itself, or the varnish separately in some other way. The life criterion is dielectric failure at a level (over 500 volts per mil) which is considerably higher than is normally imposed on insulation of this sort. There are some applications of varnished glass insulation where the glass serves only as a spacer and the varnish needs to add no dielectric strength. It is difficult, if not impossible, to see how the test under discussion is a measure of the varnish life where its function is in the spacer category. The manner in which the varnished glass samples are heated is also very arbitrary. In many applications at first, the varnished glass might be flexed considerably when put into place; during operation it might be flexed only slightly. It might be abraded to some extent or subjected to the possible corrosive effects of metals with which it comes into contact in a machine. All of these are factors which play no part in the test method, but which might be very important factors in apparatus.

Mathes and Morgan[7] and Plettner and Currin[8] have suggested that the varnish should be elongated by mild flexing, by about 1 per cent to simulate strains occurring in service. Experience has indicated that such flexing (over a 1-inch mandrel) reduces the observed varnish life on glass cloth to about half. The introduction of an arbitrary small amount of flexing in such a test can be rationally justified and should be more thoroughly explored to determine the amount most similar to the application conditions.

That the test measures the relative life of the combination rather than the varnish itself is shown in Fig. 2. Here the base materials (glass, cloth, mica paper, and asbestos paper, each 2 mils thick) are compared, each impregnated with the same silicone varnish to a total thickness of 5±1 mil. All of the tests to be discussed from this point were made with this thickness material. The difference in the dielectric strength life between the glass cloth and the other base materials is considerable.

The mica and asbestos papers also show a different type of trend of dielectric strength with aging time with a silicone

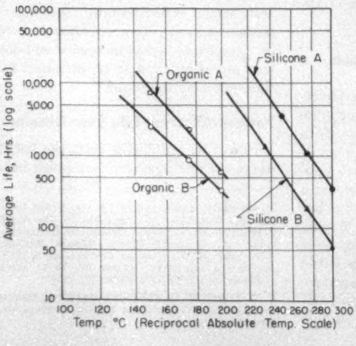

Fig. 1 (left). Thermal life of varnishes on glass cloth, 50-per-cent dielectric strength failure

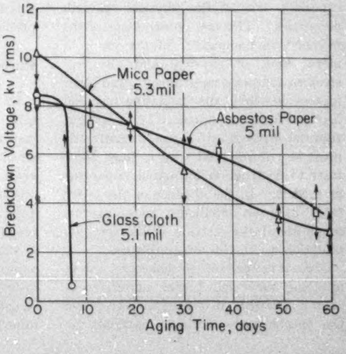

Fig. 2 (right). Effect of aging at 300 degrees centigrade on the dielectric strength of several base materials impregnated with a silicone resin

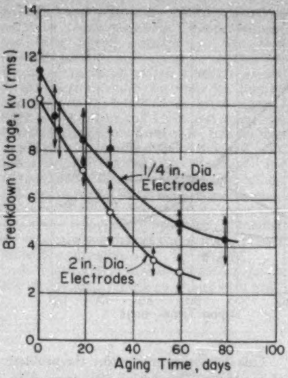

Fig. 3. Effect of aging at 300 degrees centigrade on the dielectric strength of mica paper impregnated with a silicone resin

varnish. The glass cloth exhibits, after a period of time, a sudden drop in dielectric strength from near the original value to a low value, in many spots about that of air, while the other base materials demonstrate a more gradual decline in dielectric strength. In the case of the glass cloth, cracking can occur at one time completely through the thickness of the varnish in streaks parallel to and between the glass threads.

This behavior of glass cloth with this silicone resin dispels any question of what level of dielectric strength should be regarded as a failure point. The conventional organic resins and some other silicone varnishes which have been tested with glass cloth do not show the sudden decline in dielectric strength but demonstrate a more gradual decline.

The mechanical stresses imposed on the varnish appear to be less in the mica paper and asbestos paper where the mineral particles are weakly held to each other and are able to expand and contract with the varnish. The paperlike structure seems to prevent cracks extending at one time completely through the sheet. The mica paper shows an aging characteristic peculiar to it: the varnish layer on either side of the mica paper cracks separately into small scales which tend to curl up. This does not seem to affect the integrity of the impregnated mica beneath.

Another important factor in the results obtained on a dielectric strength test of this sort is the electrode area. The electrode area is especially important when testing a nonuniform material having defects such as mentioned in the foregoing. The cracking phenomenon is a random effect which in itself introduces defects of varying depth. These will show a distribution in size with a few very deep cracks This leads to a more rapid decline in dielectric strength values with large electrodes, as shown in Fig. 3. The larger defects are more likely to be encompassed by a large electrode.

Application of data from tests of this sort to predict the behavior of similar insulation in an apparatus where much larger areas are involved must be done with care to consider the distribution of test results If a good distribution curve is obtained by a large number of tests with small electrodes, the probable breakdown value with an area equal to that exposed in a machine can be predicted. The distribution curves for the breakdown of aged and unaged silicone-impregnated mica paper are shown in Fig. 4. The distribution of breakdown voltages with 1/4-inch electrodes and with 2-inch electrodes are compared, with the voltages plotted on a logarithmic scale to emphasize the large percentage difference between the tests with 2-inch electrodes and 1/4-inch electrodes on the aged material as compared to the unaged. These breakdown voltage data do not show a normal distribution when plotted either on a linear or a logarithmic scale versus the normal probability integral scale used on the abscissa in Fig. 4. To follow a normal distribution, the data would need to fall on a straight line on such a plot.

High humidity is frequently a factor encountered with machines in service. It is important when following a shutdown period where the machine has been allowed to cool and the insulation absorbs moisture. In Fig. 5, the dielectric strength and dissipation factors of an oil-modified alkyd varnish on asbestos paper are shown as they vary with aging time and after exposure to high humidity. The effect of the moisture absorption after aging is quite appreciable on both the dissipation factors at 35- and 90-per-cent relative humidity respectively. In fact, the dissipation factor at 90-per-cent relative humidity rose so high as to become impractical to measure with accuracy. The dielectric strength at the high humidity was remarkably lower, probably as a result of dielectric heating of the sample during the test. These tests were made after 20 hours of humidification and the dielectric strength was determined with a 2-kv-per-second rate of voltage rise.

The rate of moisture absorption on exposure to high humidity is an important factor in considering the effect of such exposure. In many situations, equilibrium may not be reached for weeks. This is especially true of thick insulation. Even in the case of the 5-mil insulation

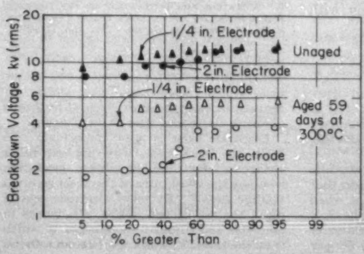

Fig. 4 (left). Distribution of breakdown voltage of silicone-impregnated mica paper

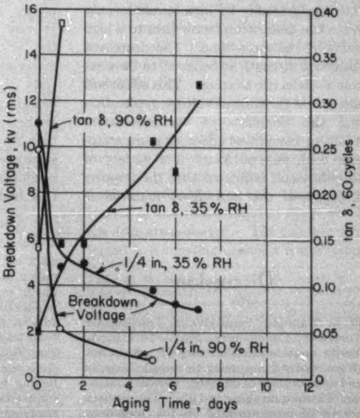
Fig. 5 (right). Effect of aging at 225 degrees centigrade on the electrical properties of an oil-modified alkyd varnish on asbestos paper



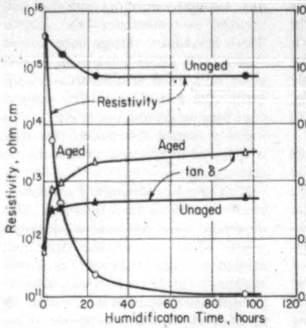


Fig. 6 (left). Effect of humidification on electrical properties of a silicone varnish on mica paper unaged and aged 30 days at 300 degrees centigrade

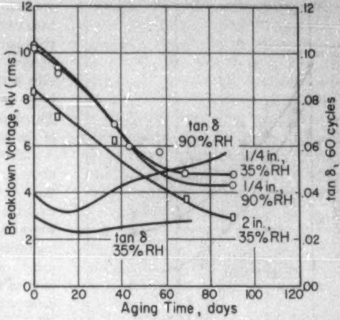
Fig. 7 (right). Effect of aging at 300 degrees centigrade on electrical properties of a silicone varnish on asbestos paper



tested here, the equilibrium is not quite complete in 24 hours. This is illustrated in Fig. 6, with data on silicone-varnish-impregnated mica paper.

Silicone-varnish-impregnated insulation of this sort appears to be much less moisture-sensitive, even at equivalent dielectric strength conditions, than conventional organic-varnish-impregnated insulation. This is illustrated by a comparison of Fig. 5 with Figs. 6 and 7. In Fig. 7, it can be noted that the level of the dissipation factor of the insulation at 90-per-cent relative humidity was still less than 0.10 even at the longest aging time, whereas with the organic varnish on the same base material, asbestos paper, the dissipation factor rose high above 0.5 even with relatively short aging times. The dielectric tests of Figs. 5 and 7 were made after 20 hours of humidification at 90-per-cent relative humidity.

It has been observed in a good many cases that the dielectric strength is reduced appreciably by high humidity only when the dissipation factor rises to a high value at the same time. The decreased dielectric strength is believed to be a result of dielectric heating. This effect will depend on the time of voltage application and the thickness of the insulation. Tests on humidified and aged resin materials with mineral fillers of a variety of sorts have all indicated that the impulse strength of the humidified material is not appreciably lower than the impulse strength of the same material dry. The 60-cycle strength, however, is much lower with humidification if the dissipation factor is high. This fact is important to remember when planning tests on humidified aged insulation. If overvoltages in practice are restricted to surges of short duration, then it would not be sensible to make overvoltage proof tests with 60-cycle voltages.

Summary

An attempt has been made to point out a number of factors affecting the results and the applicability of dielectric tests as a measure of insulation aging and life. The discussion has been directed particularly at a dielectric test on sheet insulation, but much of what has been said can indirectly apply to other aging tests on insulation. In its present form, the test can be regarded only as a measure of the relative life of insulating varnishes and not of the absolute life. It may possibly become a measure of the absolute life with particular base materials when satisfactory functional tests of these varnishes in apparatus or models are made to permit correlation. In the application it would seem necessary that something more than air dielectric strength be required as the function of the insulation to obtain a correlation with this test.

This discussion may make the problem of evaluating insulation life seem complicated but it is felt that, at this stage of the approach to the problem, it is better to recognize such variables than to ignore them and proceed rapidly to some wrong conclusions. In the end it seems inevitable that, if any positive result about the life of insulation materials is to be reached, some arbitrary decisions must be made, but these decisions should be made in the light of as much information as possible.

Discussion

M. L. Manning (Pennsylvania Transformer Company, Canonsburg, Pa.): This paper merits consideration in that it points out the necessity for pausing to consider results and applicability of dielectric tests as a measure of insulation aging and life. The authors are to be congratulated on the open-door policy in making decisions in the light of as much information as possible. Summary papers like this are of much use in evaluating various test methods.

In the section "Factors Affecting the Life Test Results," the statement is made that electrode area is especially important when testing nonuniform material. In Fig. 3, a comparison of 1/4-inch and 2-inch diameter electrodes is made showing about 60 per cent reduction in dielectric strength for 2-inch diameter electrodes after 60 days' aging.

Electrode area is most important. To make the issue clear, why not use roller electrodes for flexible sheet insulation whereby the whole area of the sheet receives voltage stress? By roller electrode test, I mean the use of two rollers, $2^1/_2$ inches in diameter and about 2 inches less in width than the sheet, in which the bottom roller is grounded and voltage is applied to the upper roller. A sheet speed of 7 feet per minute has been found satisfactory. By this method, guesswork is removed in that no doubt exists about omitting weak portions of the sheet in which improper bonding of the resin to the glass fibers has occurred. Such a test before and after heat aging has been found most satisfactory for transformer application. Usually, about 20 per cent lower dielectric strength has been found for fibrous glass base resin bonded materials by roller tests, than by 2-inch diameter electrode tests. Weak portions of the sheet area often are not found by 2-inch diameter electrodes, even though the material is said to be homogeneous.

A transformer pancake winding offers severe voltage stresses on major high-voltage to low-voltage barrier insulation structures. Experience has demonstrated that high-temperature insulating materials in barriers have not failed even on overvoltage tests if the roller electrode test was used on component insulation.

T. W. Dakin, H. M. Philofsky, and **W. C. Divens:** As Mr. Manning indicates, we have indeed tried to look critically at the thermal aging test procedures which are developing rapidly and may in the future serve as a basis for the temperature rating of insulating materials. We should like to be sure that any new basis for rating or classifying materials is placed on as solid a foundation as reasonably possible. Mr. Manning has emphasized one of the factors that is the area of the test or the relative sample size. This is important in any test of insulating materials which are to be used in large areas in an apparatus. The complete area proof test referred to is certainly desirable in ensuring a satisfactory performance. But the damage of the insulation in a proof test where corona occurs should be guarded against. This has been shown to be a factor in some cases in using alternating voltages for proof testing.

In applying the results of any sample test to larger area applications the minimum expected value should be used. If the dispersion of results in the smaller sample test is obtained carefully, it is in principle possible to predict this expected minimum value with a calculable degree of confidence, without actually measuring it.

Functional Evaluation of Magnet Wire Insulation

E. L. BRANCATO
MEMBER AIEE

R. S. PHILLIPS
ASSOCIATE MEMBER AIEE

Synopsis: A procedure developed at the Naval Research Laboratory to evaluate the thermal aging properties of magnet wire is presented. The method adopts a coil specimen and subjects it to such stresses as are experienced by the insulation system of a motor. The various factors which influence the aging properties of magnet wire are investigated. Aging data collected by this procedure are presented for a number of standard magnet wires.

THE past few years marked the development of a logical approach toward a functional evaluation of an insulating system.[1] The reference is representative of this tendency. This approach recognizes the necessity of imposing operational conditions upon any test method designed to measure expected insulation life. The Laboratory has long realized this necessity and, in fact, it has originated a method providing a functional evaluation of magnet wire.[2]

It is recognized that the magnet wire structures employed in electric equipments are generally exposed to a number of deleterious conditions. These conditions embrace temperature, voltage, humidity, contaminants, and mechanical stress. The latter stress results from vibration and from the expansion differentials of the system's components. It follows, then, that a functional evaluation of magnet wire must reflect the effects of all the operational conditions which serve to destroy, in time, the integrity of the insulation sheathing around the metallic conductor.

Coil Specimens

The specimen chosen consisted of a coil structure, Fig. 1, on a transite coil form *a* made by winding 100 feet of no. 26 American Wire Gauge insulated wire at a winding tension of 8 ounces. A 2-foot length of the same wire *b*, wound bifilarly with the coil wire at its physical center, is used to apply a dielectric stress to the insulation to detect insulation failures and, also, as a means of determining the temperature of the coil in the area of failure by resistance rise. Four-inch leads are brought from each of the two coils. At less than 1/8-inch distance from the coil form on each dielectric wire another 4-inch lead is attached. These wires serve as a current and potential leads for use with a Kelvin bridge. The main coil leads are used for heating.

Fig. 2 shows 20 identically wound coils rigidly mounted 1/4 inch apart on a 3/4-inch-diameter brass mandrel. This mass is wrapped with one layer of asbestos tape *a* which not only dampens any excessive vibrations set up in the coil leads *b* but also helps to minimize the temperature gradient caused by the difference between the coil temperature and the ambient temperature. The temperature gradient is reduced at each end of the mandrel by the addition of dummy asbestos tape coils *c*. The mandrel is mounted on a holder *d* which is constructed to make possible the removal of a group of coils from the test control circuit merely by disengaging several multijack connectors *e*. The holder makes it possible to solder all connections on the bench and to prepare another set of coils while the first set is on test. At the termination of a test, one holder can be immediately replaced by a second holder, permitting continuation of tests with minimum delay.

Test Procedure

Heating of Coil Specimens

The coils are self-heated by a 60-cycle-per-second current flowing through the 100-foot section. Unavoidably, temperature gradients exist over the coil section; however, the variation in temperature over the 2-foot length of dielectric wire is negligible. Since the observed failures are always between this wire and the heating coil, the aging temperature is measured by the resistance rise of the dielectric wire.

A bank of constant-potential transformers to minimize the normal line-voltage variations supplies the electric energy to heat the coil specimens. Temperature transients within the coils are further reduced by the temperature inertia of the brass mandrel upon which the coils are mounted. The coils are subjected to a constant ambient temperature

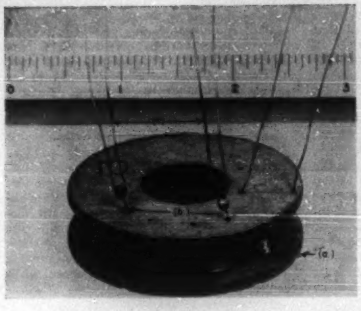

Fig. 1. Specimen coil

Fig. 2. Coil-mounting rack

of 60 degrees centigrade (C) provided by suitable ovens.

VOLTAGE STRESS

A voltage stress is established between the short dielectric wire and the heating coil with the application of 35 volts d-c, a maximum encountered in low-voltage circuit motors.[3]

HUMIDITY AND TEMPERATURE CYCLING

The heat-aging period is chosen to give the specimen an average life of 10 to 15 cycles. An aging cycle includes a series of exposures consisting of periods of heat aging, cooling to ambient, and humidification for approximately 48 hours in an ambient of 100-per-cent relative humidity at 35 C. A humidification period of 48 hours was found to be the minimum amount of time required for a complete moisture penetration of the coil.

VIBRATION OF COIL SPECIMEN

Even when aged insulation becomes brittle, it requires some form of mechanical stress to rupture the insulation film. Since electric equipments generally experience vibration during their operation, the coils are subjected to this form of mechanical stress. The magnitude of the vibration was fixed at 1.5 g's, which figure represents the average value obtained from a survey of a large number of 3,600-rpm motors.[2] The coil holders are therefore mounted on a vibration table during aging to provide this acceleration with a total displacement of 0.008 inch at 60 cycles per second.

NUMBER OF SPECIMENS

Those who study the properties of insulation systems know well that no single specimen can be considered representative of its class. Several coils apparently identically prepared and stressed will show an inherent spread in life about some mean point. The dispersion of failures about the mean point is caused by inhomogeneity of the dielectric materials, variable film thicknesses, and unavoidable differences in the preparation of the specimens. In addition to these factors, there are other statistically random effects such as those caused by impracticability of controlling temperature closer than ±2 C. Although it follows that the larger number of specimens the more representative the results will be, practical limitations restrict the number to 20 coils, a number which is felt to provide a sufficiently accurate statistical aging curve.

TEST CONTROL SYSTEM

A test panel, Fig. 3, provides individual coils with current control, dielectric stress, temperature measurement means (by the resistance rise method), and failure detection system. The dielectric stress is applied between the dielectric wire and the heating coil by a direct voltage source. Insulation failure is sensed by the rupture of a fuse in series with the dielectric wire. A recorder, which is in series with a circuit-sampling synchronous switch, indicates time of coil failure. The coils are sampled for failures periodically every half-hour or hour, depending on the expected life of the insulation.

Evaluation of Test Procedure

The majority of film-type insulations experience a definite sequence of effects when thermally aged. As the insulation begins to age, the volatile fractions of the dielectric material are driven off and the remaining material begins to embrittle. Concurrently with the process of embrittlement, shrinkage stresses usually are developed in the material. Eventually, the combined stresses caused by shrinkage and thermal expansion cause the embrittled film to crack. With additional aging the cracks become extended, thereby weakening the adhesion of the insulation to the wire. At this stage the vibration assumes a major role in the process of degradation. The action is one of loosening the cracked insulation

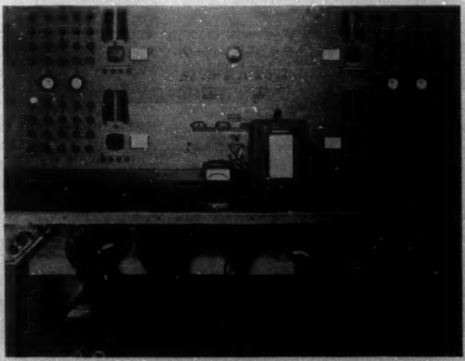

Fig. 3 Coil test control panel

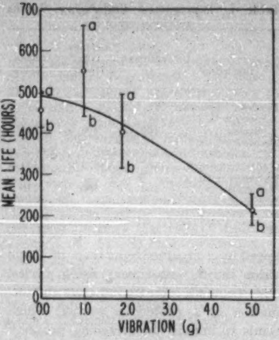

Fig. 4. Effect of vibration on life of Formvar-insulated coils at 160 C, 35-volt d-c stress. Lines a-b represent 95-per-cent confidence interval of the mean

and accelerating the flaking process. This procedure also helps to dislodge the loose insulation between conductors and, eventually, permits the establishment of metal-to-metal contact between them.

Because of the importance of vibration, a study was made to determine effects of vibration intensity on the life of insulation. Coil specimens were stressed at predetermined amounts of continuous vibration. The values chosen for test were zero, 1.0, 1.9, and 5 g's maximum acceleration at 60 cycles per second. A group of 20 coils of heavy Formvar insulation mounted on a test rack were aged at each value of vibration. The duty cycle consisted of 100 hours aging at 160 C followed by 64 hours of 100-per-cent relative humidity at 35 C. The dielectric stress for all specimens was 35 volts d-c.

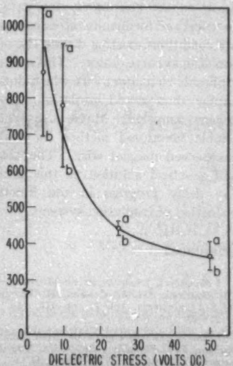

Fig. 5. Effect of voltage on life of Formvar-insulated coils at 160 C, 1.0-g vibration. Lines a-b represent 95-per-cent confidence interval of the mean

The results of this test, as seen in Fig. 4, reveal a decreased life with an increase in vibration. The effect is accentuated at the higher values of vibration. However, it should be recognized that vibration was not the only source of mechanical stress. The shrinkage-with-age and thermal expansion forces were sufficient to limit the life without the presence of induced vibration. If it were not for these latter forces, the life at zero vibration would be much greater.

Voltage stress is another factor influencing the life of insulation. A study of voltage effects was conducted on 4-coil assemblages, each consisting of 20 coils of heavy Formvar. The four groups of specimens were aged simultaneously at 160 C, but each group was stressed at different levels of voltage as follows: 4.5, 10, 25, and 50 volts d-c respectively. Each coil assemblage was aged at a duty cycle similar to the one described in the vibration tests and was subjected to a constant vibration of 1.0 g. The results shown in Fig. 5 reveal a strong dependence of insulation life on voltage stress. For example, increasing the dielectric stress from 10 to 25 volts causes a reduction of approximately 35 per cent in the mean value of insulation life.

EFFECT OF CYCLING AND HUMIDITY ON INSULATION LIFE

A spectrum of motor duty cycles ranges from very-short-time duty to continuous operation. The humidity exposures under these various conditions range from low to high. To determine the relative effects of the various conditions on the life of insulation, three types of operating procedures were chosen for investigation.

The first condition represented continuous-duty operation whereby the equipment is maintained at a rated temperature until failure occurs. No changes in temperature were permitted during these tests. The second condition, named cycling-without-humidity operation, consisted of a heat-aging period followed by a cooling period in which the specimens were allowed to reach room temperature at a relative humidity of less than 50 per cent.

The third condition, called cycling-with-humidity operation, consisted of a heat-aging period followed by a period of high humidity. After the heat-aging period, the samples were cooled to room temperature and placed in a chamber of 100-per-cent relative humidity for approximately 2 days. In choosing a duration for the heat-aging period, enough time was allowed to give the specimens an average life of 10 to 15 cycles of heat-aging and cooling.

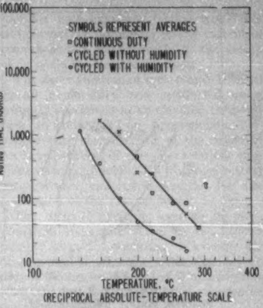

Fig. 6. Average life of Formvar coils

Aging tests were conducted on heavy Formvar insulation at the three conditions described in the foregoing. All specimens were subjected to identical conditions of vibration and voltage stress. The results of these tests are presented graphically in Fig. 6. It will be noted that very little difference in life was obtained between the continuous-duty and the cycling-without-humidity operations. However, the cycling-with-humidity tests revealed considerably less insulation life. This agrees with the generally accepted view that humidity is a sensitive probe for locating weaknesses in insulation. According to this view, corresponding insulation weakness must have occurred in the specimens subjected to continuous-duty and cycling-without-humidity operations; the absence of a searching agent delayed the sensing of failures until the insulation was sufficiently aged to flake off and allow the establishment of metal-to-metal contact. It is not excluded, however, that humidity is more than a probe and contributes to the deterioration.

COIL-AGING CYCLE

It becomes apparent from the results of these investigations that the factors contributing to the degradation of insulation must be incorporated in the procedure intended for an evaluation of the thermal-aging characteristics of magnet wire. These factors, in addition, must be introduced at such levels of magnitude most nearly simulating average operating conditions of electric equipment. With these thoughts in mind, a magnet-

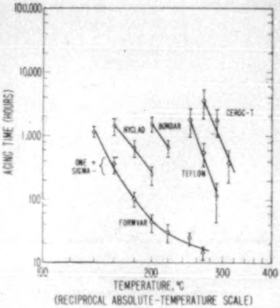

Fig. 7. Aging characteristics of magnet wire insulations

wire-aging technique was standardized to permit running 10 to 15 aging cycles to evaluate the average life. The aging cycle includes a thermal-aging phase wherein the specimens are concurrently subjected to 35-volt d-c electrical, and 1.5-*g* vibrational stresses. Following the thermal phase, the coil specimens are cooled to room temperature and, subsequently, exposed to a 100-per-cent relative humidity ambient for approximately 2 days. At the end of the humidity phase, the coil specimens are immediately returned to the thermal-aging phase and the aging cycle is repeated.

Aging Characteristics of Magnet Wire Insulations

Several types of magnet wire insulations were evaluated using the above aging cycle. These insulations were: Teflon, Ceroc-T, Bondar, and Nylclad. In addition, the effects of varnish on the aging properties of a Formvar type of magnet wire were determined.

When Teflon-insulated wire first became commercially available, an evaluation disclosed it to have very erratic characteristics. This behavior was attributed to poor bonding as was evidenced from the examination of specimens of unaged wire. Acquisition of better wire was made at a later date and consistent results were obtained. These results are presented in Fig. 7.

Ceroc-T insulation consists of an inner layer of ceramic material and two outer layers of Teflon. The ceramic material provides the insulation with high-temperature stability and prevents the pull through type of failure (typical for Teflon insulation). The Teflon cover protects the ceramic material from abrasion and reduces moisture absorption. A magnet wire with this combination of materials was evaluated in coil form and was found to possess life that is many times greater than Teflon alone.

For comparison, data are also presented in Fig. 7 for the newer types of magnet wire insulation, namely Bondar and Nylclad.

Magnet wire is seldom used without the addition of a varnish which adds greatly to the reliability of the electric equipment. The effect of varnish on the life of a Formvar insulation was determined on two sets of coils which were dipped in commercial varnishes and baked, then aged at 160 C according to standard procedure. One set was impregnated with a class-*A* clear baking varnish and the other set was treated with a silicone varnish. The aging results are shown in Table I and indicate that the organic varnish doubled the life of the insulation. The silicone varnish had no effect on the life of the Formvar, thereby making this more expensive varnish unsuitable for use with certain class-*A* materials.

Problem of Glass-Served Magnet Wire

Class *B*, glass-served magnet wire was also aged at various temperatures, giving erratic results. When operating at temperatures ranging from 220 to 290 C, the first coil failures usually occurred at approximately 1,000 hours regardless of the temperature. The subsequent failures were very erratic, with the majority of coils experiencing very long life. This erratic nature is inherent in that glass fibers serve as an effective separator, which breaks down only under certain unusual conditions to establish metal-to-metal contact. It is apparent that actual motors with glass-served magnet wire usually experience failures resulting from surface contaminants rather than from the embrittlement and flaking procedure occurring in film-type magnet wire. A number of commercial laboratories have experienced the same difficulty on motors and, consequently, they have established as a criterion of failure, a marked drop in the "wet" insulation resistance. The authors' experience with magnet wire specimens has not yet proved this criterion to be successful. It has been found that the marked drop in resistance occurs too soon after aging begins, resulting in a pessimistic value of insulation life. In a number of cases the drop in the wet insulation resistance was followed by a progressive increase in ohmic value during subsequent aging cycles. The resistance increase indicates the formation of a protective coating which tends to inhibit the searching property of the voltage stress.

Table I. Impregnated Coil-Aging Results

Insulation	Temperature, C	Average Life, Hours	Sigma, Hours
Formvar + General Electric *9574* varnish	160	800	105
Formvar + Dow Corning *997* silicone varnish	160	372	114
Unimpregnated Formvar	160	360	110

The coil-aging technique does not provide for contaminants of sufficient quantity to bridge the gaps of the glass-insulated conductors; therefore this aging technique must be considered unsuitable for evaluating these types of insulation. It is apparent that a different criterion of failure for glass insulation must be developed.

Summary

In this paper the effects of temperature, voltage, humidity, and mechanical stress upon the aging properties of magnet wire are described. It is observed that humidity plays a dominant role influencing the aging characteristic. However, this characteristic is also a sensitive function of voltage and vibration stress. A method of evaluating magnet wire has been adopted which places special emphasis on the continuous application of electrical and mechanical stresses to simulate conditions existing during the operation of an average motor. This method is applicable to magnet wire which does not employ glass-served insulation. To the authors' knowledge there is, as yet, no reliable functional method to evaluate glass-served magnet wire. The absence of a practical solution to this problem may delay progress in the functional evaluation of insulation systems.

Discussion

L. E. Sieffert and H. P. Walker (United States Navy Department, Washington, D. C.): The method presented appears to cover similar ground to that discussed in the paper by Currin and Dexter.[1] One may possibly supplement or replace the other. It is highly desirable that additional work be undertaken to determine the extent to which these methods may be employed, and the results of each method correlated with studies on motorettes and motors. To determine the place that each of these test methods may have in final evaluation as a component of a system, it would appear that much additional test data, obtained under the varying conditions at different laboratories, must be studied. These should include varnished treatment of coils.

1. A Method for Evaluation of Thermal Stability of Magnet Wire Enamel, C. G. Currin, J. F. Dexter. *AIEE Transactions*, vol. 74, pt. I, May 1955, pp. 227–32.

William T. Gordon (Westinghouse Electric Corporation, Lima, Ohio): The test procedure described seems quite adequate for the singular purpose of the evaluation of magnet wire insulation under conditions similar to those experienced in a motor. I believe that the evaluation of the separate components of an insulation system is often a necessary supplement to the evaluation of the complete system. In the final analysis, however, it is the ability of all components to function as a system which determines their suitability as motor insulation. Accordingly, the importance of testing complete insulation systems as described in the AIEE Standard must be recognized.[1]

The paper states that the heat-aging period was chosen to give the specimen 10 to 15 cycles. How is this accomplished? In the course of testing a number of samples have any survived 15 cycles or 1,500 hours of heat aging? Are the dummy coils removed during the humidification phase of a cycle?

Table I is very interesting. The results recorded clearly show the importance of proper selection of impregnating varnishes for use in an insulation system. One explanation for the failure of the silicone varnish to improve the insulation life of the Formvar-wound coils might be that the deleterious effects of the varnish-curing temperature on the enamel film offsets the gain in life to be expected from the varnish.

It is the independent or collective efforts of the manufacturers and users of electrical equipment such as those described in the paper which will go far toward making a science of the application of insulation.

E. L. Brancato and R. S. Phillips: Mr. Sieffert's and Mr. Walker's comments bring into proper perspective the spirit in which the paper was presented. The coil-testing procedure involves a number of complexities not inherent in the method described by Mr. Dexter in his report (see reference 1 of Mr. Sieffert's and Mr. Walker's discussion). It is our conviction that the technique employing twist specimens is an excellent and simple method for obtaining a measure of the relative thermal stability of magnet wire while the coil testing procedure provides a prediction of insulation life as may be obtained in a magnet wire structure of a system. More work is being done at the Naval Research Laboratory to compare the two methods but it is hoped that other members will obtain experience and data to permit a more thorough comparative evaluation of the methods.

Appreciation is expressed for the encouraging remarks of Mr. Gordon. We cannot help but concur with his conclusion that the real measure of the quality of an insulating component must be judged ultimately by its behavior in a complete system. It is the hope of the authors that the acquisition of a more comprehensive knowledge of the mechanisms of deterioration in insulation together with improved testing techniques will permit the functional test of individual components to help directly in the design of an optimum insulation system.

The determination of cycle length is based on an exploratory test conducted on a group of specimens at an elevated temperature to establish an approximate life-temperature characteristic of the material. An extrapolation of this characteristic provides sufficient information to choose testing temperatures and cycle lengths for the evaluation of the magnet wire.

The 10 to 15 cycles to average life mentioned in the paper refers to the desired number of cycles occurring to average life of a group of 20 coils. The first failure usually occurs at the end of 5 aging cycles while the last failure may have endured as many as 20 cycles.

The construction of the coil-mounting rack does not allow the removal of the dummy coils or the asbestos tape covering during the humidification phase of the cycle. We had discovered, by insulation resistance measurements, that the porous tape does not act as a very effective moisture barrier and permits absorption of moisture by the coils. However, the tape will prevent the formation of visible condensate on the insulation surface.

The possibility that the baking of the silicone varnish will cause sufficient initial aging of the Formvar magnet wire to reduce the operating life below that obtained with conventional varnish is an interesting one. During the analysis of the resulting data, this possibility was considered and it was concluded that the baking of the varnish contributed negligible aging. The curing of the silicone varnish was done at 150 C for a total period of 35 hours. If the 10-degree aging rule is employed, this time may be converted to an equivalent time of 17.5 hours at 160 C. The addition of this time to the hours life, indicated in Table I, will give an approximate total of 390 hours of life for Formvar magnet wire impregnated with silicone varnish. This value is still significantly below the corresponding value of 800 hours obtained for Formvar magnet wire aged at the same temperature, but impregnated with a compatible varnish.

An All-Magnetic Audio Amplifier System

J. J. SUOZZI
ASSOCIATE MEMBER AIEE

E. T. HOOPER
ASSOCIATE MEMBER AIEE

ALTHOUGH magnetic amplifiers have been used as audio amplifiers, the necessity of generating the high carrier frequency has made their use impractical. The objection to the use of rotating machinery to produce this carrier is the mechanical problem introduced by moving parts, while the use of the vacuum-tube oscillator as a high-frequency source introduces the disadvantages of fragility, short life, and increased maintenance problems. Although switching transistors associated with saturable reactors can be used to produce a high-frequency carrier, problems of performance and reliability arise because of the early stage of development.

Since the primary advantages of the magnetic amplifier are its ruggedness, reliability, and static nature, it would be advantageous to use it with a high-frequency power supply of essentially the same nature. Such a carrier source is the static frequency multiplier consisting of transformerlike devices and capacitors. However, in the past when these have been used, the resulting unit was prohibitively large and introduced much distortion into the system. The combination of static multipliers of improved

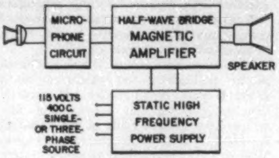

Fig. 1. Block diagram of the magnetic audio amplifier system

design with the half-wave bridge-type magnetic amplifier[1,2] has led to the development of an audio system of practical size, low distortion, and good bandwidth.

The High-Frequency Power Supply

The audio system consists of a static, high-frequency power supply, a half-wave bridge-type magnetic amplifier, and suitable input and output circuits working from a 400-cycle-per-second (cps) 115-volt single- or 3-phase source. A block diagram of the system is illustrated in Fig. 1.

The high-frequency power supply consists of cascaded frequency triplers of the magnetic core type. This type of frequency multiplier has been in use for some time. In 1913, a single-phase transformer-type frequency tripler was described by Joly.[3] Later, the single-phase bridge-type frequency tripler was developed by Von Bronk[4] in Germany. A polyphase magnetic frequency multiplier was introduced by Huge[5] in 1947 and other variations of polyphase multipliers were shown by Alexanderson et al[6] in 1948 and Logan[7] in 1950. Further discussions of the use and cascading of frequency multipliers have been made by Harriott,[8] Geyger,[9] and Johnson and Rauch.[10]

From this wealth of information, work was begun on the development of a static high-frequency source to drive a magnetic audio amplifier. A primary consideration was to minimize the physical size while producing sufficient power with a good sinusoidal wave form. Consequently, a carrier of 10,800 cps was chosen since this would entail the least amount of frequency multiplication while allowing a sufficient bandwidth to be obtained when using a half-wave magnetic amplifier. Obviously higher fidelity can be obtained by a further increase in the carrier frequency.

To obtain this carrier from the 400-cps mains, three frequency triplers were cascaded. All of the three basic types of triplers with modifications and design changes were used in various combinations. Figs. 2 and 3 show the circuit diagrams of each.

Up to the present time there have been two general methods of operating the 3-phase tripler. One method[5] utilizes only saturable reactors in each of the three phases while taking the output across a load in the neutral lead; see Fig 2(A). This output wave form appears, as shown in Fig 2(E), when a sharply saturating material with a rectangular hysteresis loop is used. The other method,[6] Fig. 2(B), utilizes a linear reactor and capacitor combination with the saturable reactor in each phase to produce third and higher harmonics. It has been shown that the use of a linear reactor alone in series with the saturable reactor is desirable for wave-shaping purposes; see Fig. 2(C). However, the addition of these three linear reactors increases the size of the unit considerably. To obtain the advantages of this method of wave-shaping without excessive increase in size, the authors have used only one linear reactor with three separate windings, as shown in Fig. 2(D). This improvement is possible because of the switching action of the saturable reactors. Since in this 3-phase system only one saturable reactor will be saturated at any instant of time, the linear reactor is effectively in only one phase at a time. The output of the tripler can be fed into a tuned circuit to obtain a better sinusoidal wave form. In this case, only a capacitor is used for tuning.

The 3-phase tripler is highly efficient. Efficiencies (watts out divided by watts in) as high as 98 per cent have been obtained. The 3-phase tripler used in the power supply for the audio system has an efficiency of 90 per cent.

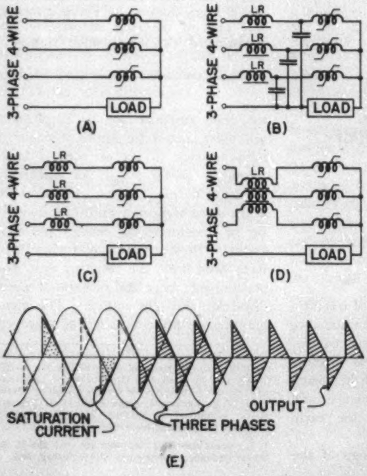

Fig. 2 (left). Circuits and wave forms of the 3-phase tripler

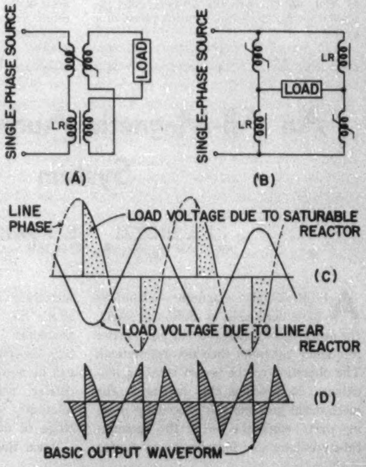
B—Bridge-type single-phase tripler
C—Superposition of the sinusoidal and distorted wave forms
D—Basic output wave form before tuning



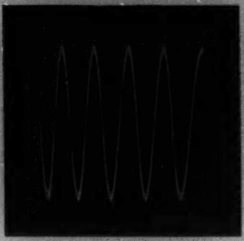


Fig. 4. Output wave form of 10,800-cps power supply

The operation of the single-phase triplers depends on the superposition of a sinusoidal and distorted voltage or current. A linear reactor is used to produce the sinusoidal voltage and necessary phase shift while a saturable reactor produces the desired distorted wave form. The superposition of the two is accomplished by the transformer-type circuit,[3] Fig. 3(A), or the bridge-type circuit,[4] Fig. 3(B). Fig. 3(C) shows the two wave forms contributed by the action of the linear and saturable reactors while Fig. 3(D) shows the basic output wave form which is a summation of the two. This output is rich in third harmonic and by means of appropriate tuned circuits can be made sinusoidal.

l, 74
1
55

Simple and improved design techniques have been developed to obtain maximum efficiency with a minimum of size. Efficiencies (watts out divided by watts in) of 85 per cent have been obtained with the single-phase tripler. The efficiency of each single-phase tripler used in the power supply of the audio system was 70 per cent. However, to improve the wave form, a sacrifice in power was made in the third tripler reducing its efficiency to 35 per cent.

Consequently, the high-frequency power supply, consisting of a 3-phase tripler followed by two single-phase triplers, used in the audio system has an over-all efficiency of 21 per cent which compares favorably with many vacuum-tube power supplies. Efficiencies almost as high can be obtained when three single-phase triplers are cascaded.

The output of the high-frequency power supply is 25 watts at 40 volts of 10,800 cps with a harmonic distortion of less than 5 per cent. An oscillogram of this output wave form is shown in Fig. 4. Double this power output can be obtained with some increase in harmonic distortion, as explained in the foregoing. This output has been achieved in a package size of only 4 by 5 by 6 inches.

The Magnetic Audio Amplifier

The magnetic amplifier designed for operation with the high-frequency power supply must possess certain characteristics. Its power demand must be low since limited power is available, and overdriving the carrier source will produce distortion and spurious frequencies in the audio output. Also, the amplifier should draw little or no direct current from the source since this too disturbs the operation of the frequency multiplier and produced distortion. A further requirement for the amplifier is a bandwidth sufficiently high to reproduce satisfactorily audio signals.

To meet the foregoing requirements, a 2-stage half-wave magnetic amplifier[1,2] was chosen. Each stage consists of two saturable reactors, appropriate selenium rectifiers, and other static components. The power drain was kept below 25 watts while the two stages were designed symmetrically to draw approximately the same amount of direct current, thus appearing as an a-c load to the power supply. The a-c power gain of the amplifier is approximately 1,000 while the physical size including the microphone circuit components is $1\frac{1}{2}$ by 5 by 4 inches.

The transfer function of the half-wave magnetic amplifier includes a dead-time function ϵ^{-st}, where t is the time delay. The dead time is $1\frac{1}{2}$ cycles of the carrier frequency for the 2-stage amplifier. This produces a linearly increasing phase distortion which is of no consequence in the audio system since the ear cannot detect the phase angles of the various frequency components.

The complicated nature of control in the magnetic amplifier is such as to cause both frequency and nonlinear distortion under certain conditions. These effects are apparent upon referring to the wave forms of Fig. 5. By nature the magnetic amplifier is controlled during some presetting period. In this case, this period occurs during alternate half-cycles of the carrier. The portion of the signal that is effective in controlling the amplifier is phase-reversible, the phase and magnitude of the output on each half-cycle is determined by the phase and magnitude of the effective control half-cycle. For signal frequencies below half the carrier frequency, e.g., 3,600 cps as shown in Fig. 5(A), the output is essentially 3,600 cps. At half the carrier frequency, i.e., 5,400 cps, the output is either 5,400 cps, as in Fig. 5(B), or zero, as in Fig. 5(C), depending on the phase of the signal with reference to the carrier. For signal frequencies greater than half and less than the carrier frequency, e.g., 7,200 cps, the output is seen to contain a large component of 3,600 cps; see Fig. 5(C). This beat frequency between the signal and carrier frequencies is the source of the nonlinear distortion mentioned in the foregoing. In addition, for signal frequencies approaching half the carrier frequency, reduced output is obtained depending on the relative phase between the signal and the carrier.

Despite these adverse effects caused by the nature of the amplifier, the over-all frequency and nonlinear distortion of the amplifier working from the frequency multiplier is less than 10 per cent over the bandwidth of the system. This is exclusive of the carrier which was suppressed by an appropriate filter. A plot of distortion measured on the amplifier working from its magnetic power supply is shown in Fig. 6(A).

The bandwidth (3 decibels down) of the

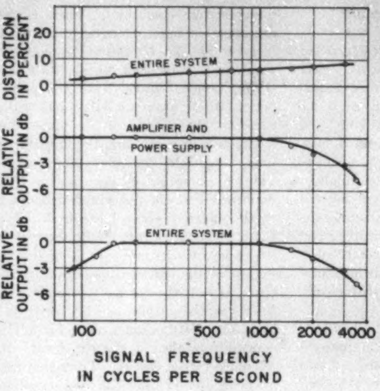

Fig. 6 (left). Performance curves of the magnetic audio amplifier system

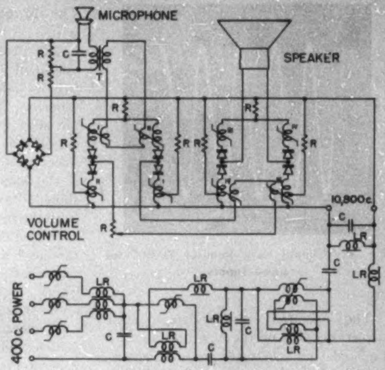

Fig. 7 (right). Complete schematic diagram of the magnetic audio amplifier system

magnetic audio amplifier is zero to 3,000 cps, as indicated in Fig. 6(B). The upper limit of this bandwidth is determined by the detrimental phase shift discussed, and stray capacitance in the amplifier. It is to be noted that the lower limit of the bandwidth goes to zero in that the half-wave magnetic amplifier functions as a d-c amplifier.

Performance of the Audio System

The schematic diagram of the entire audio system is shown in Fig. 7. The amplifier is driven by a carbon microphone and suitable transformer. The direct current for the microphone circuit is obtained by rectifying and filtering a portion of the 10,800-cps voltage. The output of the amplifier is fed directly into the voice coil of a permanent magnet speaker. The physical size of the entire unit can be seen in Fig. 8. The amplifier and power supply can be combined in a package 5 by 5 by 6 inches.

The bandwidth of the entire system is 90 to 3,000 cps, as seen in Fig. 6(C). The fall off below 90 cps is attributable to the input circuit and the frequency response of the speaker.

The audio output power is 2.5 watts with less than 10-per-cent distortion over the frequency range. This system possesses all the advantages of magnetic amplifiers, i.e., reliability, ruggedness, long life, instant warm up, and a usable temperature range limited only by the selenium rectifiers. Because of the instant warm-up characteristic, the system will operate with no stand-by power since the unit need be excited only when voice amplification is desired. Thus, a push-to-talk switch could be used as an on-off power switch. This would result in the complete elimination of quiescent power and the attendant heat dissipation problem.

A further by-product of this characteristic is the possibility of derating the frequency multiplier and amplifier with a resultant decrease in size when the duty cycle permits. The unit described in this paper was designed for 100-per-cent duty cycle, a condition not often encountered. With the additional advantages of potting the entire amplifier and power supply, an audio system of complete dependability and long life can now be realized.

Conclusions

The construction of an all-magnetic audio amplifier system is entirely feasible both in size and performance. In ruggedness, dependability, and long life, such a unit should excel all others presently known in the art. At present, this type of audio system is suitable for intercommunication, facsimile reproduction, public address, and battle command systems. As higher source frequencies become available, this solution to the audio amplifier problem will find wider application.

Discussion

E. Lehtonen (Sperry Gyroscope Company, Great Neck, N. Y.): The single 3-winding reactor shown in Fig. 2(D) does indeed offer some economy of material compared to the three separate reactors shown in Fig. 2(C). However, the 3-winding reactor is effectively a single-winding reactor since the windings are presumably tightly coupled. This point is more clearly seen in Fig. 7 where the three reactor windings are shown with a common connection. The voltages at the left-hand end of the windings are effectively at the same potential, neglecting current-resistance drops. If the left-hand ends were joined together, either lower losses could be achieved or a smaller reactor could be used.

This parallel-connected reactor corresponds to the reactor L_s in Figs. 1, 2, and 3 of the paper by Smith and Salihi.[1]

Reference

1. Analysis and Design of a Magnetic Frequency Multiplier, O. J. M. Smith, J. T. Salihi. *AIEE Transactions*, vol. 74, pt. I, March 1955, pp. 99–106.

J. J. Suozzi and E. T. Hooper: We wish to thank Mr. Lehtonen for his very worthwhile observation. We should, however, like to add the following comment.

When a separate reactor is used in each phase, as in Fig. 2(C), both wave shaping and protection from excessive circulating currents are obtained should the 3-phase source become umbalanced and cause two saturable reactors to be saturated simultaneously.

When using only a single-winding reactor in the neutral lead, such as L_s in Figs. 1, 2, and 3 of the paper by Smith and Salihi, only wave shaping is obtained.

Considering the 3-winding reactor in Fig. 2(D), it is seen that the separate reactors are a special case of this configuration, i.e., zero coupling. Of course, zero coupling can be obtained by using separate reactors. It is further seen that the single-winding reactor is also a special case of the 3-winding configuration, i.e., essentially perfect coupling, as Mr. Lehtonen points out.

In addition, with coupling between zero and perfect, any desired combination of characteristics can be obtained. Therefore, utilizing this configuration with less than perfect coupling, both wave shaping and protection against circulating currents can be obtained. The size, of course, depends on the amount of coupling and the demands of the circuit.

Empirical Equations for the 60-Cycle Spark-over Gradients in Commercial Oil

W. F. GAUSTER
MEMBER AIEE

INTENSIVE experimental work on dielectric phenomena in liquids has been done during the last 40 years. There is considerable interest on the engineer's part in obtaining reliable information about the dielectric properties of liquids, especially of commercial oil, used as insulation and as a cooling medium for transformers, circuit breakers and much other electrical apparatus. Many valuable experimental results have been obtained for dielectric strength, corona, dielectric losses and other dielectric properties of commercial oil.[1–5] In connection with the first-mentioned problem, that of the dielectric strength or oil, numerous details have been carefully studied: for example, the influence of electrode geometry, the rate of voltage rise, humidity, dissolved gases and different kinds of contamination. However, as Whitehead has mentioned,[6] "Breakdown in liquids could readily become a compendium of unrelated observations" because very little was known about the physical background of this field.

Only recently, experimental technique has been so much improved that reproducible results for the impulse breakdown strength of carefully purified liquids for small electrode spacings could be obtained.[7,8] Physical models have been used to explain the dependence of the measured dielectric strength of liquids on electrode spacing[9] and on the molecular structure.[10,11] Furthermore, experimental work has been done on impulse corona in commercial oil,[12] which seems to be a good start for studying the physical phenomena involved in electrical breakdown of oil.

However, these results cannot yet be applied for finding numerical values of 60-cycle spark-over gradients for different electrode geometries in commercial oil. Therefore, it is interesting to attempt to interpret basic empirical data on the dielectric strength of commercial oil from an entirely different point of view. Several applications of "weakest link" probability theory to insulation variability have been made.[13,14]

W. R. Wilson developed a theory of the equivalent volume[15] and applied it to different electrode geometries. Unfortunately, as shown in this paper, this application of the theory of probability to spark-over in commercial oil does not lead to the desired results. It still seems necessary to use purely experimental data and to consider carefully appropriate empirical equations until a more general presentation of such relationships is achieved.

Empirical Equations for Oil Spark-over Gradients for Sphere Gaps of Various Radii

The results of an extensive series of experiments on the spark-over voltages of sphere gaps in commercial oil, performed with 60-cycle alternating voltage, are contained in Table LXIV (page 220) in reference 1. Sphere radii R from 0.159 to 6.25 centimeters (cm), and spacings x from 0.129 to 5.08 cm were used; and values for the spark-over voltage V and for the maximum spark-over gradient G were listed. The average spark-over gradient in the gap, measured along the axis connecting centers of the spheres, is

$$G_{av}=\frac{V}{x} \qquad (1)$$

The maximum spark-over gradient, which occurs at the intersections of the axis with the sphere surfaces, is

$$G=fG_{av}=f\frac{V}{x} \qquad (2)$$

The factor f is a function of the ratio ξ of the spacing x to the radius R.[16] In this paper only the case of symmetrical potential distribution (neither sphere grounded) is considered. With one sphere grounded, a different factor f_1 must be used.

Tables for the numerical values of $f(\xi)$ have been calculated.[17] The factor f does not consider any field distortion resulting from space charge. Peek states that for each value of the radius R the spark-over gradient G reaches a minimum value G_{min}, which corresponds to a horizontal (constant) part of the breakdown curve at sufficiently large spacing x. In Fig. 182 and Table LXVIII he listed these minimum spark-over gradients G_{min} and shows that these data can be expressed by an empirical equation

$$\{G\}_{min}=28.3\left(1+\frac{4}{\sqrt{R}}\right)\text{kv}_{max}/\text{cm} \qquad (3)$$

Paper 55-65, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing November 30, 1954.

W. F. Gauster is with North Carolina State College, Raleigh, N. C.

The author wishes to acknowledge the valuable comments of J. Hagenguth, T. W. Liao, and K. H. Weber, and the assistance of D. S. Burton; and to thank Dr. A. Roth for providing supplementary data for the experiments performed by the Brown Boveri Company, Baden, Switzerland.

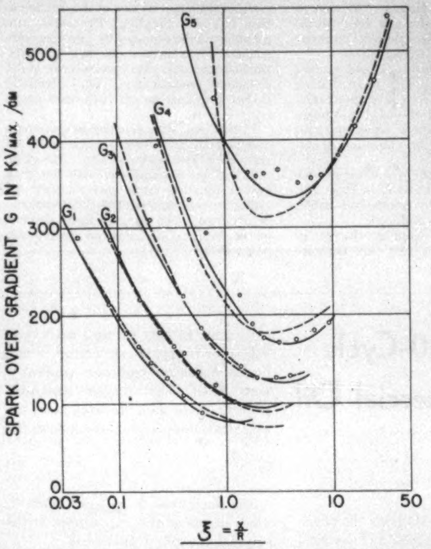

Fig. 1. Sixty-cycle spark-over gradients G_k of sphere gaps in oil for different radii R_k and spacings x. Encircled points are Peek's empirical data. Solid curves are best fitting parabolas, dashed curves are calculated with equations 9 and 10

with an error not greater than ±10 per cent (%). Calculated values are expressed by enclosing the letter between brackets { } or [ ]. Observed values are indicated by the letter without brackets.

To discuss Peek's experimental results for sphere gaps in oil in greater detail, a different physical parameter in the plot of the breakdown gradients will be used, which has often been applied to sphere gaps in gases.[18,19] This is shown in Fig. 1 where the spark-over gradients are plotted against $\log x/R = \log \xi$ (here log means logarithm to the base 10), instead of x as in Peek's book. The different points shown represent the experimental data from Peek's table LXIV. For each value $R_k = R_1, R_2 \ldots R_5$ of the radius R a smooth solid curve is drawn. They can be represented by equations of the form

$$\{G\} = \{G_{\min}\}(R) + N(R)\left[\log \frac{\xi}{\xi_0(R)}\right]^2 \qquad (4)$$

If ξ is plotted on a logarithmic scale, the curves are parabolas which are symmetrical about the vertical lines drawn through the vertexes $G_{\min}$ with the abscissas $\log \xi_0$. If a linear scale for ξ is used, the curves are very steep for small values of ξ, and become more and more flat for large values of ξ. Curves of this kind, observed for spark-over gradients in air, are shown by Whitehead.[20] It must be remembered that the ratio $G/G_{av} = f(\xi)$ used here is defined for symmetrical spheres infinitely far from ground, a condition, of course, never fully realized in practice. The numberical values of G for small values of R and large values of ξ should be used with caution because in these cases the connecting leads and the proximity of the tank walls will distort the electrostatic field of the sphere gap.[17]

The minimum values of the spark-over gradients $G_{1\,\min}$, $G_{2\,\min}$, and $G_{4\,\min}$ plotted in Fig. 1. are taken from Peek's experimental data as listed in his table L XVIII. $G_{3\,\min}$ and $G_{5\,\min}$ are between the experimental values and those calculated with Peek's equation 3. The values $N(R_k)$ and $\xi(R_k)$ are chosen so that equation 4 fits the experimental data for G as closely as possible. This was done by trial and error, because an evaluation with the use of the principal of least squares is too involved here. The following empirical equations have been used and the results are listed in Table I.

$$\left.\begin{aligned}
R_1 &= 6.25\ \text{cm};\ \{G_1\} = 82 + 90\left(\log \frac{\xi}{1.3}\right)^2\\
R_2 &= 3.12\ \text{cm};\ \{G_2\} = 98 + 100\left(\log \frac{\xi}{2.2}\right)^2\\
R_3 &= 1.27\ \text{cm};\ \{G_3\} = 125 + 110\left(\log \frac{\xi}{3.5}\right)^2\\
R_4 &= 0.555\ \text{cm};\ \{G_4\} = 169 + 170\left(\log \frac{\xi}{4.0}\right)^2\\
R_5 &= 0.159\ \text{cm};\ \{G_5\} = 335 + 210\left(\log \frac{\xi}{3.8}\right)^2
\end{aligned}\right\} \qquad (4A)$$

These equations represent the set of Peek's empirical data with deviations of less than ±10%. Obviously, this representation is not unique, since the coefficients $N(R_k)$ and $\xi_0(R_k)$ could be assumed in an appropriate way with values somewhat different from those shown in the foregoing and, nevertheless, a satisfactory approximation of the experimental data would result. The next goal should be to find simple empirical forms for the coefficients $N(R_k)$ and $\xi_0(R_k)$, similar to that in equation 3 for $\{G_{\min}\}$. For example, in the case of sphere gaps in air it is known that the spacing x_0, below which the apparent strength G begins to increase, is represented by the equation[21]

$$x_0 = 0.54\sqrt{R} \qquad (5)$$

Therefore, for air

$$\xi_0(R_k) = \frac{x_0}{R_k} = \frac{0.54}{\sqrt{R_k}} \qquad (6)$$

If it were possible to find similar empirical forms for $\xi_0(R)$ and $N(R)$ for sphere gaps in oil, then equation 4 alone would be sufficient for calculating the spark-over gradient for any value of R and ξ. However the empirical data available up to now for sphere gaps in commercial oil are inadequate to provide conclusive results when the foregoing method is used. Therefore an alternate method was developed as in the following.

Empirical Equation Representing Peek's Complete Set of Data for Sphere Gaps in Oil

It is possible with sufficient accuracy to find one single empirical equation which represents the complete set of Peek's data for sphere gaps in oil if we proceed in the following way: From equation 3 it follows that

$$(\{G_{\min}\} - 28.3)\sqrt{R} = 113.2 \qquad (7)$$

is a constant. A numerical evaluation of the term $(G - 28.3)\sqrt{R}$, where G now means the experimental value of the spark-over gradient for any value of R and ξ, shows that this term is a function of ξ alone (a similar empirical law was used by Whitehead for sphere gaps in air.[22]) to a fairly good approximation

$$(G - 29.3)\sqrt{R} = F(\xi) \qquad (8)$$

All the points contained in Peek's Table LXIV are considered in Fig. 2. A best-fitted curve is then drawn for $F(\xi)$. The vertex of this curve has the co-ordinates log 2.5 and 113 kv$_{\max}$/cm. The left and right branches of the curve can be approximated by parabolas of different slope, expressed as

$$\left.\begin{aligned}F(\xi)&=113+165\left(\log\frac{\xi}{2.5}\right)^2\ldots\xi\leq 2.5\\ F(\xi)&=113+\ 70\left(\log\frac{\xi}{2.5}\right)^2\ldots\xi\geq 2.5\end{aligned}\right\}\qquad(9)$$

If $F(\xi)$ is known, G is found by means of equation 8, put in the form

$$[G]=28.3+\frac{1}{\sqrt{R}}F(\xi)\qquad(10)$$

With the empirical equation 10 it is possible to compute the spark-over gradient with good approximation for any value of R and x contained in Peek's Table LXIV. These values are designed by $[G_k]$ and are listed in Table I. The results are not as accurate as those obtained by applying equations 4, but the accuracy seems to be sufficient if the relatively poor reliability of the experimental data is considered. In Fig. 1 the values $[G_k]$ computed with equations 9 and 10 are shown by means of dotted curves. The minimum values $[G_k]_{\min}$, obtained with these equations, follow exactly the values $\{G_{\min}\}$ resulting from Peek's equation 3.

Empirical Equation Representing Another Set of Experimental Data for Sphere Gaps in Oil

Fig. 33.6 of reference 3 shows the results of experiments for 60-cycle spark-over gradients of sphere gaps in commercial oil. The sphere radii were 3.125 and 6.25 cm, and spacings over the range 2.0 cm $\leq x \leq$ 40.0 cm were used. These experiments supplement Peek's results in an interesting way, because the experiments were performed under entirely different circumstances with oil of a different characteristic. The maximum spark-over gradients G were calculated from the spark-over voltages V by means of the same coefficients f (for symmetrical potential distribution, with both spheres insulated from ground) used by Peek.

The spark-over gradients are listed in Table II. For the minimum spark-over gradients $G_{\min}$ a relation having the form of equation 3 is expected

$$\{G_{\min}\}=A+\frac{B}{\sqrt{R}}\qquad(11)$$

Using the values $R_1=6.25$ cm, $G_{1\ \min}=70$ kv$_{\max}$/cm, and $R_2=3.125$ cm, $G_{2\ \min}=87$ kv$_{\max}$/cm, the values of the coefficients A and B are determined so that equation (11) becomes

$$\{G_{\min}\}=29+\frac{102.5}{\sqrt{R}}=29\left(1+\frac{3.53}{\sqrt{R}}\right)\qquad(12)$$

It is seen that the coefficients are not very different from those in equation 3.

$\{G_2\}$	110	92	87.5	87	88	90	94.5	100	105	110	115

ξ	0.4	0.8	1.2	1.6	2.0	2.4	3.2	4.0	4.8	5.6	6.4	8.0	9.6	11.2	12.8
$F_1(\xi)$	202.5	147.5	122.5	112.5	105	102.5	102.5	102.5	105	107.5	110				
$F_2(\xi)$		143		112.5		102.5	102.5	105	109.5		118.5	128	138	148.5	161
$F(\xi)$	196.5	143.0	122.0	111.5	106.5	103.5	102.5	104.5	107.5	111.6	116.0	125.0	134.0	143.0	151.5

In a similar way as for equation 8 two functions $F_1(\xi)$ and $F_2(\xi)$ are now defined by

$$(G_1-29)\sqrt{R_1}=F_1(\xi) \text{ and } (G_2-29)\sqrt{R_2}=F_2(\xi) \quad (13)$$

The numerical values listed in Table II show that the difference between these two functions is relatively small and therefore both can be approximated by means of one function $F(\xi)$

$$F(\xi)=102.5+123\left(\log\frac{\xi}{3.0}\right)^2 \quad (14)$$

Substituting this value in equation 13 the spark-over gradients $\{G_1\}$ and $\{G_2\}$ can be obtained

$$\{G_1\}=29+\frac{1}{\sqrt{R_1}}F(\xi)=70+49.2\left(\log\frac{\xi}{3.0}\right)^2 \quad (15)$$

and

$$\{G_2\}=29+\frac{1}{\sqrt{R_2}}F(\xi)=87+69.7\left(\log\frac{\xi}{3.0}\right)^2 \quad (16)$$

The numerical values of the calculated spark-over gradients $\{G_1\}$ and $\{G_2\}$ are listed in Table II. The difference between these calculated values $\{G_1\}$ and $\{G_2\}$ respectively, and the experimental results G_1 and G_2 respectively, is smaller than 5%. There is also little difference between the spark-over gradients of sphere gaps as cited by Roth and those measured by Peek.

Spark-over in Oil Between Concentric Cylinders

Peek's three series of experimental data, listed in his Table LXVII,[1] were obtained for outside cylinders of radii of 3.81, 6.67, and 11.42 cm respectively. The no. 6 Transil oil used for these experiments is characterized by a dielectric strength of 58 kv_{max} between standard disks 0.5 cm apart. Since the values of the spark-over gradients between spheres shown in Table LXIV refer to no. 6 transil oil with 58.5 kv_{max} spark-over voltage between standard disks 0.5 cm apart, it might be assumed that both series of experiments were performed with oil of similar characteristics. Peek mentioned that the tests with $R=6.67$ cm, and $R=11.72$ cm were made on short cylinders where the field was somewhat disturbed. However, if the spark-over gradients G_1 which occur at the surface of the inner cylinder with the radius r are plotted against log r (a logarithmic scale for r is used to show clearly small values of r), the experimental values for $R=3.81$ cm and $R=6.67$ cm can be closely approximated by the same smooth curve, which is indicated in Fig. 3 as solid curve G. For $R=11.72$ cm only a smaller number of experiments were performed. They show a relatively high scattering and they will not be used for the following consideration.

Peek derived for $R=3.81$ cm an empirical equation for the maximum spark-over gradients (in kv_{max}/cm) between concentric cylinders

$$\{G\}=36\left(1+\frac{1.2}{\sqrt{r}}\right)=36+\frac{43.2}{\sqrt{r}} \quad (17)$$

which is shown in Fig. 3 with the dashed curve $\{G\}$. It fits the experimental results for $R=3.81$ cm and for $R=6.67$ cm closely as long as values of the inner radius r larger than 0.2 cm are considered. For 0.032 cm the experimental value G is about 50% higher as predicted by equation 17; see Table III. From Peek's experiments it seems to follow that the radius R of the outside cylinder and the length L of both concentric cylinders influence only very little the values of the spark-over gradient G.

Analytical Form of the Theory of the Equivalent Volume

Up to now only purely empirical forms for the 60-cycle spark-over gradients in commercial oil have been discussed. Experimental results have been represented by means of simple equations without any attempt to find basic principles. As mentioned before, it does not yet seem possible to use the results obtained recently for spark-over in highly purified liquids and for impulse corona in commercial oil for these problems. Therefore, the only resort at present is to apply the theory of probability for numerical calculations of the spark-over in oil.

Wilson[15] has developed the theory that the primary factor which determines the dielectric strength of commercial oil of controlled quality around electrodes of different geometries is the volume of that oil under stress. Applying considerations which are basically statistical, he concludes that for small volumes of oil, statistical variations are large and unit dielectric strengths are high. For large volumes at wide spacings, lower unit dielectric strengths must result, but statistical reliability and reproducibility are greatly improved. Beyond these qualitative statements Wilson attempts to show that the numerical values of the dielectric strength of any geometrical electrode arrangement may be obtained from test data on a sphere gap with the same equivalent volume. The equivalent volume V_e is enclosed between each electrode and the equigradient surfaces at which the stress is about 90% of the maximum value. For oil of a given characteristic (considering oil quality, humidity,

dissolved gas, solid and liquid contamination, and including details of the performance of the experiments such as rate of voltage rise, rest time between tests, etc.) there should be one definite function

$$[G]=f(V_e) \tag{18}$$

Peek's empirical equation 3, already used, states that $\{G_{min}\}$ for sphere gaps in oil is a linear function of the reciprocal value of the square root of the sphere radius R. Wilson assumes that the spark-over gradient G_{min} occurs for a gap spacing x_0 approximately equal to $2R$, or $\xi_0=2.0$, and in this case the equivalent volume is found to be approximately

$$V_e=0.4R^3 \text{ or } R=1.35\sqrt[3]{V_e} \tag{19}$$

Since it is assumed that only one definite function $f(V_e)$ determines the spark-over gradient G, there must be, in general, for an oil whose quality is characterized by equation 3

$$[G]=f(V_e)=28.3\left(1+\frac{4}{\sqrt{1.35}\sqrt[3]{V_e}}\right)=28.3+\frac{97.5}{\sqrt[3]{V_e}} \tag{20}$$

This analytical form, not contained in Wilson's paper, yields the same values as shown in his graph 2. It is supposed to hold for oil of a special characteristic which is determined by the numerical values shown in Peek's Table LXIV. This oil will be designated as oil of characteristic 1 in subsequent discussion. In general, one expects for commercial oil of another characteristic (cf. equation 11) an expression

$$[G]=A+\frac{B/\sqrt{1.35}}{\sqrt[3]{V_e}} \tag{21}$$

This should be valid for any electrode arrangement provided that the definition for the equivalent volume already defined can be applied, for instance, for sphere gaps with any gap spacings. It cannot be used for electrodes with sharp edges (see reference 3, page 133, Fig. 33/8), because in this case the gradient at the edge assumes an infinite value.

For symmetrical sphere gaps with small spacings ($\xi \leq 0.1$) Wilson indicates an equation[15] for the equivalent volume V_e (his equation 7), which can be written

$$V_e=0.372\xi^3R^3 \tag{22}$$

For $\xi=2$, the value $V_e=0.4\ R^3$ has already been used. In general, for any ratio $\xi=x/R$ the equivalent volume V_e can be expressed by

$$V_e=S(\xi)R^3 \tag{23}$$

This equation is a similarity law.

If equation 23 is substituted in equation 21 it follows for the spark-over gradient of sphere gaps

$$[G]=A+\frac{B/\sqrt{1.35}}{\sqrt[3]{S(\xi)}\sqrt{R}} \tag{24}$$

For small spacings the special form

$$[G]=A+\frac{B/\sqrt{1.35}}{\sqrt[3]{0.372}\sqrt[3]{\xi}\sqrt{R}} \tag{25}$$

is obtained.

The equivalent volume of concentric cylinders with an inner radius r and the length L is

$$V_e=0.75Lr^2 \text{ (cf. Wilson's equation 8)} \tag{26}$$

Therefore the spark-over gradient (with concentric cylinders) is

$$[G]=A+\frac{B/\sqrt{1.35}}{\sqrt[3]{0.75L}\sqrt[3]{r}} \tag{27}$$

Finally, for parallel, cylindrical disks with the radius R and the spacing s, an equivalent volume $V_c=R^2\pi s$ is obtained, and therefore, (with cylindrical disks)

$$[G]=A+\frac{B/\sqrt{1.35}}{\sqrt[3]{\pi s}\sqrt[3]{R}} \tag{28}$$

It is seen that for the most important cases of electrode geometries the theory of the equivalent volume brought in these equations, which are not contained in Wilson's paper, gives relatively simple laws for the spark-over gradients. These equations contain only two constants, A and B, to characterize the quality of the oil used, the rate of voltage rise, etc. In this way an approximate picture is obtained of possible forms of the equations containing the geometrical parameters which influence the dielectric strength of oil.

Theory of Equivalent Volume Applied to Sphere Gaps in Oil

Wilson's Table II shows calculations of the dielectric strength $[G]$ for spheres of 3.33-cm radius at small spacings. Using equations 23 and 20 the equivalent volumes V_e' and V_e'' and the expected values of the spark-over gradients $[G']$

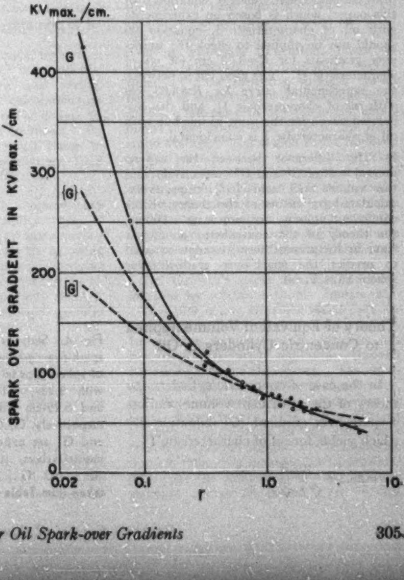

Fig. 3. Sixty-cycle spark-over gradients of concentric cylinders in oil. Points indicate Peek's experimental data for R=3.31 cm, small circles for R=6.7 cm. G is best-fitting curve for these values. {G} is calculated with Peek's empirical equation 7, [G] is calculated with equation 30

Table IV. Equivalent Volumes and Calculated Spark-over Gradients for Spheres with 3.33-, 3.12-, and 6.25-Cm Radius

ξ	2.0	0.946	0.45	0.156	0.075	0.03	0.015
V_e/cm³	14.8	5.8	2.12	0.37	0.077	0.0124	0.0031
[G]	90.5	101	114.5	143	177.5	230	282.5
V_e'/cm³	12.2	4.78	1.75	0.305	0.0635	0.0102	0.00255
[G']	92	102.5	116	147	182	237	290
V_e''/cm³	98	38.4	14.0	2.45	0.51	0.082	0.0205
[G'']	74	81	91	112	137	176	214

and [G''] for spheres with the radii 3.12 and 6.25 cm can be calculated. These values are listed in Table IV. In Fig. 4 the spark-over gradients [G], [G'], and [G''] as predicted by the theory of the equivalent volume, and the experimental values G (taken from Peek's Fig. 181), and G' and G'' (taken from Peek's Table LXIV) are plotted versus log ξ. Fig. 4 shows the following results:

1. Peek's experiments with the spheres with $R=3.33$ cm were not performed with oil of characteristic I. The expression "oil of characteristic I" considers oil quality, humidity, etc., and details of the performance of the experiments such as rate of voltage rise, rest time between tests, etc. Otherwise the experimental curve G for $R=3.33$ cm could not intersect the curves G' for $R=3.12$ cm and G'' for $R=6.25$ cm, but should be located between these two curves, and very close to the first. The oil used by Peek in his experiments with $R=3.33$ cm is designated here as oil of characteristic II, in contrast to the oil of characteristic I used for the experiments listed in Peek's Table LXIV.

2. Since both equation 20 and Wilson's corresponding graph (his Fig. 2), are derived from the numerical values of equation 3 of this paper, which is based on experiments with oil of characteristic I, equation 20 should not be applied to check the spark-over gradients for $R=3.33$ cm for oil of characteristic II. The good check between the experimental curve for $R=3.33$ cm with oil of characteristic II, and the calculated curve for the same radius but with oil of characteristic I is coincidental.

3. The difference between the experimental values G' and G'' respectively and the values [G'] and [G''] respectively, calculated by means of the theory of the equivalent volume, are very large. Hence, the theory of the equivalent volume, at least in its present form, cannot be used to predict the spark-over gradients for sphere gaps in oil.

Theory of Equivalent Volume Applied to Concentric Cylinders in Oil

In the case of concentric cylinders the theory of the equivalent volume predicts a spark-over gradient [G] (equation 27) which yields for oil of characteristic I

$$[G]=28.3+\frac{102.5}{\sqrt[6]{L}\,\sqrt[3]{r}} \qquad (29)$$

This equation compared with Peek's equation 17 results in the following:

1. The spark-over gradient should not depend on the outer radius R, according to both equations.

2. In equation 29 the gradient is a linear function of the reciprocal value of the third root of r, whereas in Peek's equation 17 the reciprocal value of the square root of r is used.

3. Equation 29 shows a weak influence of the length L of the cylinders (reciprocal value of the sixth root); in Peek's equation the length L is not contained explicitly.

In his paper, Wilson discusses the most probable length L used in Peek's experiments with $R=3.81$ cm, because no recorded values of the length could be found at that time. By careful study of details still available he concluded that the length was about 75 cm. With this value equation 29 becomes

$$[G]=28.3+\frac{50}{\sqrt[3]{r}} \qquad (30)$$

Fig. 3 and Table III show the values [G] of the spark-over gradient computed with equation 30. For inner radii $r \geqq 0.25$ cm the approximation is very good. For smaller values of r equation 30 should not be applied.

Major Problems in This Field

As mentioned previously, reliable experimental data for 60-cycle spark-over in commercial oil with different electrode geometries are very scarce. To achieve better results, refinements of the experimental technique are necessary. Even when the greatest care is taken to observe the same testing procedure (rate of voltage rise, etc.) with the same electrode geometries and with oil samples of the same qualities, the results obtained at different places and by different observers show much larger differences than might be expected.[23] It would be desirable to have series of experiments similar to those done by Peek in 1915 carried out on the basis of the improvements in testing techniques with commercial oil which have been established since that time.

Furthermore, it will be necessary not only to record the mean values of spark-over gradients but also to observe carefully the statistical distribution of these measurements. Even though it has been shown here that the application of the "weakest link" theory of probability, as presented by the theory of the equivalent volume, cannot be used successfully in this form, it is desirable to find a general principle, based on the theory of probability, which may lead to simple mathe-

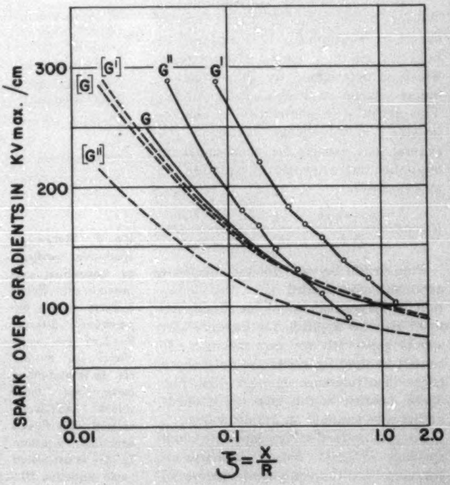

Fig. 4. Sixty-cycle spark-over gradients of sphere gaps in oil with 3.33-, 3.12-, and 6.25-cm radius respectively. G, G′, and G″ are experimental values; [G], [G′], and [G″] are taken from Table IV

matical expressions for the spark-over gradients in commercial oil. Such theoretical and experimental work on spark-over with various gap geometries might result in an improved method of testing the dielectric strength of oil.

Conclusions

1. An empirical equation is derived for Peek's experimental data on sphere gap spark-overs in commercial oil. This equation also represents with good accuracy another series of experiments with sphere gaps in oil of different quality when different numerical values of the coefficients are used.

2. When Peek's empirical equation is applied to several sets of experimental data for predicting the spark-over gradients of oil between concentric cylinders, a good correlation can be obtained for only inner radii r larger than 0.2 cm. The need for further experiments is apparent.

3. It is shown that it is not possible to check the experimental data for sphere gaps and concentric cylinders by calculations based on the theory that the dielectric strength depends on the equivalent volume of oil. However, this theory, when expressed in simple analytical forms and applied to different gap geometries, is shown to be a valuable help in obtaining an approximate picture of possible forms of equations containing the geometrical parameters which influence the dielectric strength of oil.

4. The paper points out the necessity for more and better-controlled experiments with various gap geometries which might result in an improved method of testing the dielectric strength of oil.

◆

Discussion

W. R. Wilson (General Electric Company, Philadelphia, Pa.): Dr. Gauster's paper is concerned largely with discussion of my paper[1] which introduced what is called the equivalent-volume or volume-probability theory of the dielectric strength of oil. A second paper,[2] by Wilson, Streater, and Tuohy, describing practical application of this volume theory, was presented concurrently with Dr. Gauster's paper.

Before proceeding with this discussion, the reader is urged to consider carefully the following typical experimental fact. Dielectric strength has been determined for two uniform-field test gaps (shown in the closure of reference 2 of this discussion), each with 0.1-inch metal-to-metal clearance in the same oil at the same time. The plane area of the larger electrodes, and therefore the volume of oil under stress, was 100 times that of the smaller electrodes. In air, the two gaps would have essentially the same dielectric strength. In oil, the small volume gap had an average dielectric strength of 36 kv rms, but the large volume gap with the same metal-to-metal clearance had an average dielectric strength of only 22 kv rms. This large reduction of average dielectric strength is a reproducible result of the probability relationships of the first volume-theory paper[1] and can be estimated from equation 1 of that paper. The standard deviation for the small volume gap was 6.0 kv; and equation 1 yields a predicted value of 21 kv for the large volume gap in comparison with the 22-kv test value.

In the two volume-theory papers, the point of view has been as follows:

1. The unit (or spatial maximum) dielectric strength of commercial oil decreases with increasing volume of oil under stress.
2. It is important to know about how large the effect is, and the direction of its results.
3. As indicated, for example, by certain inconsistent data in Peek,[1] other effects, at present unknown, are also acting. Therefore, one should base calculations on the known performance of a design as similar as possible to the unknown. By so doing, one can come much closer to correct practical design predictions than he can if he ignores this effect.

As is shown in the two volume-theory papers, the volume-probability type of calculations check with surprising accuracy the test dielectric strengths for the following conditions: spheres at moderate spacing (Peek[1]); concentric cylinders (Peek[1]); parallel disk gaps at small spacings (Peek[1]); 3.33-cm radius sphere gap at small spacings (Peek[1]); disk gaps at large spacings (Peek[1]); spherically ended rods at large spacings (Minor[3]); capacitors with different lengths of roll;[2] and numerous practical oil circuit breakers.[2] It is concluded that these excellent checks constitute strong evidence for the existence and importance of the volume-probability effects.

However, as one of the evidences that additional factors are present, reference 1 of the discussion points out, that "even in this source (Peek), careful cross-checking between different test series reveals discrepancies. For example, plotting the data from Fig. 181 and from Table LXIV yields a pair of curves which cross."

The stated area of application of the two volume-theory papers was for the large spacings and large radii of curvature of oil circuit breakers. From reference 2 of this discussion, "reducing clearances and reducing electrode dimensions result in marked increases in statistical deviations. . . . the dielectric strength curves become so steep that for electrodes of small radius, a few per cent of error in the radius might make 50-per-cent error in the withstand voltage. This region is not involved in the problem under study, except that the calculation method and physical picture are supported by the fact that they predict both the instability and the large increases in dielectric strength." The region of Dr. Gauster's comments concerning the volume theory is that of small spacings and small radii.

Dr. Gauster's paper can now be summarized by reference to his figures. Fig. 1 is a plot of the aforementioned data on sphere gaps from Peek's Table LXIV. In addition to plotting the data, he has mathematically fitted equations, through equations 4(A), to the curves. The equations have no stated physical significance, and yield about the same information as curves drawn by eye. Fig. 2 is a different mathematical curve-fit of the same data (through equation 10) and also is applicable only to them. It includes the approximation that the minimums in the dielectric strength curves all lie at $X/R = 2.5$.

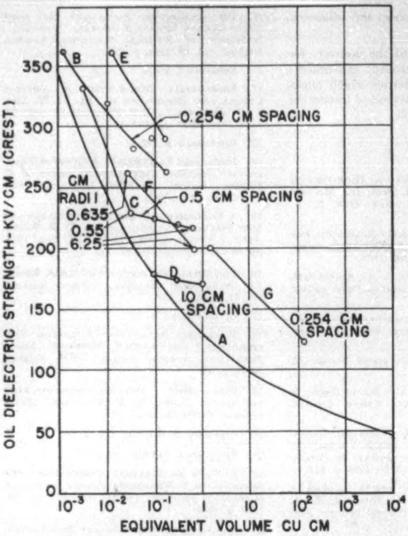

Fig. 5. Curves of dielectric strength versus volume

A—Composite curve from Peek's graphs B, C, D—From Gauster's equations, for sphere gaps at fixed spacings indicated E, F—Modern data for 0.635- and 6.25-cm radius spheres at spacings indicated G—Modern data for plane parallel gaps at 0.254-cm spacing

None of the equations can be applied to cylinders or other more general practical configurations. Depending on the condition of the oil, both the author's equations (when they apply) and the particular volume-theory curve presented will yield results that may be either higher or lower than test data by a factor of more than 2 to 1.

Fig. 3 for concentric cylinders includes the only data (except for corroborative data by Roth) not referred to in the first volume-theory paper. These data consist of the points for the three cylinders with the smallest radii ($R = 0.16$ cm and under). These points were discarded by Peek and by the writer in plotting the same curve.

Fig. 4 is the exact set of curves referred to in the first volume-theory paper: "The data from Fig. 181 and Table LXIV (Peek) yield a pair of curves which cross."

Now, in examining this figure and table which are the basis of Figs. 1, 2, and 4, one sees that Peek presented the table for the purpose of establishing the minimums in the dielectric strength curves of sphere gaps versus spacing (which occur at moderate spacing, or a spacing to radius ratio of, roughly, 2.5). These values, plotted by Peek on his graph 182, check very well with the volume theory (see Fig. 3, reference 1). However, when he discussed dielectric strengths at small spacing, he abandoned Table LXIV and used data with many more points to cover the same range. These he plotted as Fig. 181.

Thus, at low spacings, Peek rejected the tabulated data and selected those of the figure. These (and other) inconsistent results were noted in the first volume-theory paper and it was concluded that "because of the large difference in the dielectric strength of oil under conditions which are superficially identical, the absolute values cannot be applied with safety in engineering calculations for modern oil under any specific set of conditions." Dr. Gauster, however, reverses Peek, rejecting the figure data as incorrect, but then selecting the tabulated data as correct, basing his equations on them. Incidentally, both sets of data agree quite well at moderate spacing. Dr. Gauster then concludes, based on the poor correlation between the volume theory and the low-spacing tabulated data, "Hence the theory of the equivalent volume, at least in its present form, cannot be used to predict the spark-over gradients for sphere gaps in oil." And, "The good check between the experimental curve for $R = 3.33$ cm [low-spacing data selected by Peek] . . . and the [volume theory] calculated curve . . . is coincidental."

This actually lays the groundwork for an interesting example of the value of the volume theory, because it can be shown that either the volume theory is wrong, or Dr. Gauster's equations (based in part on the tabulated data rejected by Peek) are wrong at low spacings. This conclusion results simply from obtaining dielectric strength values from Dr. Gauster's equations for spheres of different radii but constant metal-to-metal spacing, and plotting them against equivalent volumes in Fig. 5. If the spacing-to-radius ratio is small, the field is essentially uniform. However, because the larger spheres will have a larger region under stress, according to the volume theory they should have a lower breakdown voltage. The results as seen in Fig. 5 indicate strong dependence of dielectric strength on equivalent volume at 0.254-cm spacing. The absolute values, of course, are quite different from those of the original paper. However, at 0.5- and 1.0-cm spacings, there are flat regions where dielectric strength does not depend appreciably upon volume, according to Dr. Gauster's equations. If this is factual, the volume theory is wrong.

To check this point, new data were taken. The oil was of course different from that used by Peek. A typical test was as follows: Two sphere gaps, one with large spheres and one with small, were placed in the same oil at the same time. Voltage was raised to breakdown, first on one gap, then on the other, until 80 test values were accumulated. This method of test permits reliable relative data to be obtained. If data are not taken with some such continuous control, the results may be remarkably inconsistent. Table V shows the data, together with the result of volume-theory calculation (see equation 1 of reference 1) of the breakdown gradient for the large spheres, based on the data for the small spheres. Many similar tests were run with similar results. Those reported in this discussion were run at 60-cycles, rapid rise.

According to Dr. Gauster's equations, the relative gradients for these two spheres at 0.5-cm spacing should be almost identical, instead of being different by 30 per cent; see Fig. 5. Consequently, it is concluded that both Gauster's equations and the data Peek rejected in Table LXIV are incorrect at low spacings, and contain inconsistencies. It should perhaps be noted that, although the absolute values of the modern data are well above those of the volume-theory curve based on Peek's data, the slopes based on the pairs of points determined under the same conditions are quite similar.

The volume theory predicts a further interesting corollary. According to it, all curves of sphere gap breakdown voltage versus spacing for spheres of different radii should cross, because at any given very low spacing the smaller spheres will have the higher breakdown voltage, but at relatively high spacing the larger spheres will have sufficiently better uniformity of field that they will have the higher breakdown voltage.

Peek's data of Table LXIV do not show this crossing. It is assumed that there was little interest in the low-spacing values for large spheres, that the series of curves

Table V. Sixty-Cycle Rapid-Rise Tests

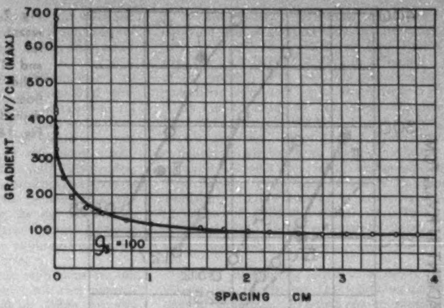
Radius, Cm	Spacing, Cm	Breakdown, Kv Crest	Gradient, Kv per Cm	Standard Deviation	Calculated Gradient	Error, %
0.635	0.254	80.0	359	51		
6.25	0.254	72.9	291		284	3
Test repeated at higher spacing						
0.635	0.508	102	259	48.5		
6.25	0.508	99	199		186	6

was drawn to the origin approximately together (Peek actually shows this in his Fig. 177), and that the points in the table were read from these curves. This was surmised at the time the first volume-theory paper[1] was written, and was the reason for using the figure data rather than the tabulated data at low spacing. This merging of curves produces the flat regions which result when Dr. Gauster's equations are plotted on Fig. 5. Roth's curves and test points (reference 3 of the paper) also show this disinclination to let the curves cross. That the curves actually can cross is shown by the fact that in the aforementioned relative data for 0.254-cm spacing, the smaller spheres had the higher breakdown voltage. Furthermore, in his Fig. 177, Peek shows disk and sphere gap curves which cross in accordance with the volume theory predictions.

Now, concerning concentric cylinders, Dr. Gauster states in conclusion 3, "It is shown that it is not possible to check the experimental data for . . . concentric cylinders by calculations based on the theory that the dielectric strength depends upon the equivalent volume of oil." However, in the body of the paper he states, concerning concentric cylinders, "For inner radii $r \geq 0.25$ cm, the [volume theory] approximation is very good."

In the applications of the volume theory, the radii have been in the order of 5 cm, or in the "very good" range. In fact, the very good range covers all of the data that Peek chose to plot on his graph, and excludes only the three points he discarded. Although several possibilities suggest themselves as to the nature of the unrecognized factor which causes the misfit at low radii, there is one factor which is known to come into play in this general range. When an electrode radius is reduced below a critical value, flashover voltage becomes independent of the radius in a manner similar to a needle gap (see Minor[1]). Therefore, the calculated gradient at flashover becomes a meaningless concept. For example, consider the two largest of the three small cylinders ($R = 0.079$ and 0.159 cm). The two corona starting voltages are 92 and 88 kv, while the two calculated gradients are 251 and 155 kv/cm.

Fig. 6. Peek's Fig. 181 showing increase of strength of oil at small spacings at 60 cycles. (Spheres, R=3.33 cm). By permission of McGraw-Hill Book Company, Inc., reference 1 of the paper



Both Dr. Gauster's paper and this discussion have been concerned primarily with negative considerations. Now it seems appropriate to look at the areas of agreement, because these are so much the greater. Corroboration for the probability effects is found in reference 13 of the paper, which was previously unknown to me. Work by Farmer is described in reference 13 in which he discusses very briefly what he assumes to be an "area effect" for relatively sharp-edged disk gaps in oil. However, he gives no evidence which bears on the question as to whether the variation is not actually with volume. At very small spacings, the volume (or area) effect is so great that breakdown apparently occurs in the low-stress, high-volume, uniform field rather than at the high-stress, low-volume edges. Breakdown voltage decreased with increasing electrode diameter, but no mathematical correlation was attempted. At higher spacings, over about 0.4 inch, the area effect was stated to disappear, obviously because of the increasing relative field concentrations at the sharp edges, in comparison with the average field. As is well known, sharp-edged electrodes (for which spacing is large with respect to edge radius) give radically lower statistical variations than rounded electrodes, so probability effects virtually disappear. Whereas Farmer deals only with average field strengths, unit dielectric strength values at the edges would be many times greater and of totally different form. Further corroboration of the existence of a volume theory was found on page 61 of reference 2 of the paper just as this discussion was being completed. A general though uncertain dependence on volume is postulated, together with speculation that sphere gap curves should cross.

* Oil between disks 0.5 cm apart tested 58.5 kv max 25 C. By permission of McGraw-Hill Book Company, Inc., reference 1 of the paper.

Judging from Dr. Gauster's oral presentation, some additional areas of agreement are as follows: probability effects are important and real; Peek's data, or data of similar scope, should be taken again with modern controls and reported; it is not certain that the probability effects now attributed solely to volume do not actually depend upon both volume and surface area; the volume theory gives a first approximate answer to what is taking place, but at present there is no known method of calculation which will give accurate results over wide extrapolations. I hope that Dr. Gauster will continue his activities and that he will separate some of the additional variables that certainly seem to exist.

In applying the volume-probability principles in their present form, if one has sufficient data to establish performance of one dielectric structure, he can calculate the performance of another fairly similar structure with good engineering accuracy. This is verified by the low calculation errors for plane and spherical gaps in this discussion, and for the ±5% accuracy realized in the practical work with oil circuit breakers.[2]

W. F. Gauster: Since both Mr. Wilson and I have based our work on Peek's Table LXIV and Fig. 181, it is worth while to reproduce these sources here, as Table VI and Fig. 6. Peek's own comments

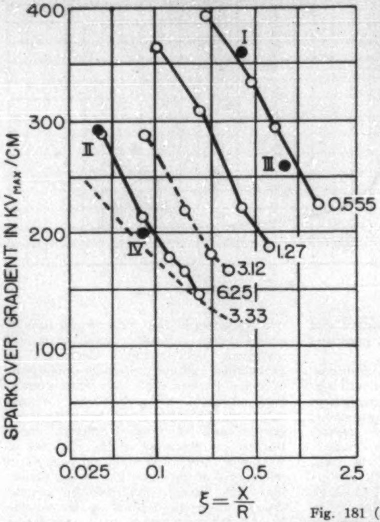

Fig. 7. Points I and III represent Wilson's experiments for R=0.635 cm, points II and IV for R=6.25 cm. Solid lines and dashed line from Peek's Table LXIV, dashed curve from Peek's Fig. 181. Radii shown in cm

(reference 1 of the paper) are as follows: "Sparkover voltages and gradients are given for various spheres at various spacings in Table LXIV. The characteristic of the curves between gradient and spacing are the same as those for air (see Fig. 42) as shown in Fig. 181." And "For the small spacings, the apparent rupturing gradient is very high, just as in the case of air. Strengths as high as 700 kv/cm have been reached." Peek's Fig. 181 (Fig. 6) shows the graph of the spark-over gradients versus spacings; however, small values of spacings can be read with some exactness only if they are not much smaller than approximately $x=0.1$ cm. This spacing corresponds to a spark-over gradient of about 250 kv$_{max}$/cm. For gradients higher than 250 kv$_{max}$/cm and spacings smaller than 0.1 cm this graph cannot be used. Peek's captions of Table LXIV (Table VI) and Fig. 181 (Fig. 6) indicate the different goals which he had in mind when he showed the different experimental data. The captions are: "Table LXIV Dielectric Strength of No. 6 Transil Oil—Sparkover Between Spheres at 60 Cycles" with the remark: "Oil between disks 0.5 cm apart tested 58.5 kv max., 25 deg. C" and, on the other hand: "Fig. 181. Showing increase of strength of oil at small spacings at 60 cycles. (Spheres, $R=3.33$ cm)." No special oil quality, and no table of numerical values of the spark-over gradient are indicated in the latter case.

Peek's obvious intention was to list in Table LXIV a set of consistent numerical values of experimental data for the dielectric strength of a special oil quality at a certain temperature, whereas the purpose of Fig. 181 was to show in a qualitative way only the typical performance at very small spacings. The difference of the two oil qualities is very obvious; oil as used for Fig. 181 ($R=3.33$ cm) has, as indicated, the dielectric strength of about 250 kv$_{max}$/cm for a spacing x approximately equal to 0.1 cm, whereas in Table LXIV ($R=3.12$ cm) as spark-over gradient of 288 kv$_{max}$/cm occurs for $x=0.264$ cm.

Nevertheless there must be no doubt of the "peaceful coexistence" of these very different sets of Peek's experimental data. Such great differences can be easily observed when fresh oil is used for one series of experiments, whereas the other experiments are performed with oil which has already been used for some time, especially when it has been kept in an open tank. Also the details of the performance of the experiments, such as rate of voltage rise, rest time between tests etc., have a great influence. These facts are clearly expressed in my paper when I introduced the designations "oil of characteristic I" and "oil of characteristic II" for Table LXIV and Fig. 181 respectively. This is also in accordance with Mr. Wilson's remark (reference 15 of my paper) that the discrepancy between the table and the figure values may be explained "perhaps because of different rates of voltage rise."

There is no doubt that all experimental data concerning dielectric strength of oil have to be used with caution, especially when details in the performance of the experiments are not indicated and when no detailed statistical evaluation of the results is shown. Nevertheless up to now Peek's Table LXIV (showing the 60-cycle spark-overs of sphere gaps in oil) from 1915 seems to be the best set of experimental data of this kind available up to now. As shown in Fig. 1 of the paper all the values of the spark-over gradient plotted against $\log x/R = \log \xi$ seem to be sufficiently consistent with each other. On the other hand, the different deviations of the points from the best-fitting smooth curves show that none of Peek's numerical values were obtained by extrapolation only. In Table LXIV, values which were not actually observed have been omitted. There are also some indications of a phenomenon, predicted with the use of his volume theory by Mr. Wilson in his discussion, namely, that breakdown voltages versus spacings for spheres of different radii should cross at very low spacings. As shown in Peek's table at $x=0.129$ cm, the breakdown voltage for $R=1.27$ cm is somewhat smaller than for $R=0.555$ cm. The same effect may exist at $x=0.264$ cm for $R=0.555$ cm, and $R=1.27$ cm respectively. However, the uncertainty of these experimental data is too high to make any definite statement. This phenomenon probably depends on the rate of voltage rise.

Considering all these facts, I cannot agree with Mr. Wilson's assumptions about Peek's Table LXIV and Fig. 181 as developed in his discussion. His hypothesis can be summarized as follows: For larger spheres Peek's Table LXIV should be correct only as far as minimum spark-over gradients are concerned. For smaller spacings of larger spheres the tabulated values should be rejected, since they were obtained by Peek by means of incorrect extrapolations. Finally the spark-over gradients shown in Fig. 181 should supplement the unrejected tabulated values in a consistent way.

The check of Mr. Wilson's volume theory for sphere gaps with small spacings would be correct only if the hypothesis mentioned in the foregoing could be accepted. Since this is not the case, my view is maintained that Mr. Wilson's check of his volume theory for small sphere spacings is not valid.

This opinion is strengthened by the results of Mr. Wilson's new experiments with sphere gaps. In Fig. 7 the spark-over gradients (in kv$_{max}$/cm) are plotted against $\log x/R = \log \xi$ similar to Figs. 1, 2, and 4. Points I and III represent Mr. Wilson's experiments for $R=0.635$ cm, points II and IV for $R=6.25$ cm. The solid lines represent Peek's tabulated values for $R=0.555$, 1.27, and 6.25 cm respectively; the dashed line represents Peek's tabulated values for $R=3.12$ cm. The dashed curve is from Peek's Fig. 181 for $R=3.33$ cm. Mr. Wilson's new experimental values for $R=6.25$ cm are very close to Peek's tabulated values for this radius, especially point II with the smaller spacing. Since Peek did not make experiments with a spacing of $x=0.635$ cm, his tabulated values for 0.555 cm and 1.27 cm are shown in Fig. 7. In case of a perfect coincidence of Mr. Wilson's values with Peek's tabulated data, points I and III ($R=0.635$ cm) should be located between these two curves, very close to that for $x=0.555$ cm. In fact, Wilson's value III has such a position. Point I is somewhat higher than expected from Peek's tabulated values, but all the differences are relatively very small and may be easily explained by different oil quality, etc., including the fact that Wilson made his experiments with rapid voltage rise. On the other hand, the curve from Fig. 181 for $R=3.33$ cm is even lower than Wilson's experimental value for $R=6.35$ cm. These details give additional proof that the hypothesis of Mr. Wilson about Peek's tabulated values and Fig. 181 does not agree with the actual facts.

Fig. 5 shows that for $x=0.5$ cm Mr. Wilson's experimental values are between 9% higher and 14% lower than those calculated with my empirical equation for the oil characteristic as used for Peek's Table LXIV. At a spacing $x=0.254$ cm the difference is between 10% and 18%. These differences are greater than those obtained when Peek's experimental data are directly used. This follows from Table I of the paper, where the differences between the values from the empirical equations and Peek's tabulated values are listed. As mentioned in this connection in the paper, the accuracy of empirical equation 9 is sufficient as far as experimental data are available up to now. As soon as better experimental data are obtained, empirical equation 4 should be used and "the next goal should be to find simple empirical forms for the coefficients $N(R_k)$ and $\xi_0(R_k)$ similar to that in equation 3 for $G_{\min}$."

Whereas the magnitude of the differences between Mr. Wilson's new experiments and Peek's tabulated values, are from 0 to 10%, and from 0 to 18% when using my experimental equation, the differences between Mr. Wilson's new experimental values I, II, III, and IV and his unit dielectric curve derived by means of the volume theory from Peek's minimum gradients (which are accepted by Wilson for this oil quality) are 56, 77, 26, and 46% respectively.

To obtain a new, complete check of the volume theory as presented by Mr. Wilson, it would be necessary to establish, for the oil quality used and the special way of performance of the experiments involved, the curve of unit dielectric strength from experiments with spheres of large spacings. It would not be sufficient to show that lines corresponding to E and F in Fig. 5 coincide with each other. They also should coincide with the unit dielectric curve derived from the minimum spark-over gradients. Mr. Wilson's new experiments do not satisfy these requirements.

When the validity of the volume theory is checked, great care must be taken. For instance, a check of Mr. Wilson's volume theory for the case of the oil breakdown strength for "isolated" spheres (large spacings) is not conclusive. Mr. Wilson's theory is based on Peek's empirical equation

$$G_{\min}=28.3\left(1+\frac{4}{\sqrt{R}}\right)kv_{\max}/\text{cm}$$

which holds for the constant part of the curve and therefore Mr. Wilson's curve for the dielectric strength of oil between isolated spheres is only another mathematical expression for Peek's empirical law.

In his discussion, Mr. Wilson refers to experiments with two uniform-field test gaps, each with 0.1-inch metal-to-metal clearance in the same oil at the same time. The plane area of the large electrodes, and therefore the volume of oil under stress, was 100 times that of the smaller electrodes. I consider this not an appropriate experimental arrangement to demonstrate the validity of the volume theory. The large difference of the dielectric strength in these two cases could also be explained easily by means of a surface effect.

Concerning concentric cylinders in oil, Peek writes (reference 1 of the paper): "It is much more difficult [than for air] to detect the starting point of corona and, unless the conductors are very small or far apart (s/r large), corona does not appear before spark-over. For instance, in the Table LXVII when the outer cylinder is 3.81-cm radius and the inner 0.0127-cm radius ($R/r=300$), the corona and spark-over voltages are practically the same. . . . The spark-over voltages and corona voltages up to fairly high ratios R/r are, therefore, the same and may be used in determining the strength of oil."

Peek disregarded the values $r=0.032$, 0.159, and 0.079 cm, not because in these cases corona occurs before spark-over, but because his empirical equation

$$\{G\}=36\left(1+\frac{1.2}{\sqrt{r}}\right)=36+\frac{43.2}{\sqrt{r}} \qquad (31)$$

gives results much too low for these values of r. As shown in Fig. 3 of the paper, the values derived by means of the volume theory are still lower.

With small inside radii r the spark-over gradients as listed in Peek's Table LXVII show a very strong dependence on r, whereas the curve representing the breakdown voltage V_s becomes flat. However, if the volume theory yields a spark-over gradient of about 145 $\text{kv}_{\max}$/cm instead of 251 $\text{kv}_{\max}$/cm, the predicted breakdown voltage is instead of 88 kv (crest) only

$$88\,\frac{145}{251}=51 \text{ kv (crest)}$$

which is about 42% too low.

Peek's empirical equation for concentric cylinders seems to be less satisfying than his empirical equation for the minimum spark-over gradients of spheres (equation 3 of the paper). Whereas this latter equation yields good results in the range from $r=0.159$ to $r=12.5$ cm (see Peek's Fig. 182 and Table LXVIII in reference 1 of the paper), Peek uses his equation for concentric cylinders in a range from $r=0.238$ cm to $r=2.540$ cm only. See his Figs. 180(A) and 180(B). For $r=5$ cm, Peek's empirical equation for concentric cylinders yields too high spark-over gradients and Wilson's value is still higher (about 30% higher than the empirical results available). The range of a satisfying coincidence of Wilson's values and Peek's empirical data is approximately between 0.25 cm$\leq r \leq$2.5 cm only; compare Table III.

Before concluding this discussion, I should like to express the following more general thoughts. The first step in physical research is to undertake experiments. In the field of breakdown in oil the need for further experiments is apparent. The second step usually is to establish empirical equations, without any immediate physical significance. For various groups of experiments, different empirical equations must be established and there will be no direct connection between these equations. The third step is to understand which physical factors are responsible for the empirical results. The ultimate goal is attained if some basic equations of physical significance can be established which yield, as special cases, equations which can be used instead of the empirical equations.

Sometimes it is a relatively easy matter to obtain the desired results by application of a general principle without the necessity to consider the physical processes in complete detail. Examples are the principle of the conservation of energy and many variation-principles, which are often applied to problems in physics.

Mr. Wilson's theory of the equivalent volume is an attempt to understand and to predict numerical results for breakdown phenomena in oil, with the use of a general principle, without trying to follow the physical processes in detail. Mr. Wilson applied in a very clear and simple way the concept of spatial probability to breakdown problems. He carefully studied the problem of whether his theory in its actual form is sufficient to check experimental results or whether other factors should be considered. There is hope that the consideration of the volume effect in an appropriate form, combined with that of other probability effects (for instance surface effects) will finally lead to a more complete theory, which will yield the desired results.

Gas and Moisture Equilibriums in Transformer Oil

OIL IS the major electrical insulation component of large high-voltage transformers. It must withstand, free of corona, the severe short-time electrical stresses imposed during factory test or abnormal service conditions, as well as the less severe normal-service stresses of long duration. It follows that best insulation design demands precise knowledge not only of the stresses imposed on the oil during test and operation, but also a sound understanding of the oil's ability to withstand successfully the stresses under a wide variety of adverse conditions.

Pure oil, free of all contaminating influences, has very high intrinsic strength, many times that practically and economically attainable in "working" transformer oil. The oil in a transformer always contains some water in solution; certain amounts of dissolved gases are unavoidable. As the transformer is operated through its normal daily and seasonal load cycles, both the water and gas content of the oil are subject to rather wide change. For optimum application of insulation, the designer must know, among other things, how water and gas content of oil are influenced by temperature, pressure and humidity; and how these two contaminants, in turn, influence the electrical strength of the oil.

Unlike air, which has such well-defined and consistent electrical strength behavior that it is frequently used for measuring voltage, the electrical strength of oil is erratic and capricious. Its apparent strength, even when left undisturbed, may change appreciably from one hour to the next, and it is not uncommon for a series of consecutive breakdown determinations made over a 15-minute interval to exhibit such broad statistical dispersion as to leave little confidence in the results. Oil strength may be influenced not only by dissolved water and gas, but by ever-present solid particles, as well as other extraneous factors which include temperature, pressure, and the nature of the electric field.

Many dollars' worth of time and effort have been expended on studies of the electrical strength of oil. Some of the factors that affect oil strength were identified qualitatively several decades ago and they include, of course, dissolved water and gas. It seems safe to say, however, that no really clean-cut, quantitative, and usable conclusions have been reached. On the contrary, the literature on these subjects is replete with contradiction.

There are three reasons for this, all involving experimental difficulties which can be stated briefly as: 1. recognition and control of all variables, 2. quantitative determination of the variables; and 3. interactions among the variables.

For several years a small group of chemists, physicists, and engineers in the General Electric Power Transformer Engineering and Laboratories Department have been working to alleviate these difficulties. Progress has been made in all three areas, and several successful well-controlled experiments have been completed which shed considerable light on oil breakdown behavior and the influences of extraneous factors. This success is due partly to the development of methods of sampling and handling oil without changing it, of precisely determining water and gas content, and of finding basic solubility relationships and equilibrium criteria for gas, water, and oil. These methods and findings constitute the subject matter of this paper in which thorough treatment is given to experimental methods employed to provide clearer understanding and validation of data presented.

Specifically, these highly transient variables have been brought under closer laboratory observation than ever in the past.[1–3] In its standardization and establishment of basic moisture and gas solubility relationships in ranges of common practical interest, this work has laid the foundation for continuing advanced study of these variables directed to a more complete understanding of their practical significance in the design, construction, and maintenance of liquid-filled electrical apparatus. It should be noted that all the experimental data on oil herein reported have been obtained on transformer oil from one particular source.

Analytical

ANALYSIS FOR WATER

Since 1935, when Karl Fischer used an iodine reagent for determining moisture in sulfur dioxide, an ever-increasing number of applications have been described until at present the Fischer reagent is the one most widely used for quantitative moisture determination. Mitchell and Smith's book, "Aquametry,"[4] comprises an excellent an comprehensive survey of the field of water analysis with particular emphasis on the Karl Fischer reagent.

Although the technique utilized for many years comprised a visual determination of color change from chromate-yellow to a red-brown iodine color, this has been found inadequate for the accuracy and precision required in any basic study involving minute quantities of water. For this reason it was decided to evaluate several of the existing electrometric procedures for end-point determination. A circuit suggested by G. R. Cornish[5] was modified and found superior to many of the more elaborate circuits described in recent years, particularly from the standpoint of simplicity and reliability. This modified circuit is shown in Fig. 1, and has been successfully employed in conjunction with a moisture-measuring apparatus in all phases of the program.

Apparatus

The apparatus is shown in Fig. 2, and consists of an all-glass titration chamber into which a burette tip, platinum electrodes, and a Teflon-covered stirring bar are fitted. An automatic burette and reservoir are utilized to titrate accurately with iodine reagent into the sealed system. The electrodes are connected to the detecting circuit by copper leads. The microammeter dial comprises the indicating instrument for end-point detection. A magnetic stirrer is used to agitate the solution during the determination.

Paper 55-66, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 21, 1954; made available for printing December 3, 1954.

R. B. KAUFMAN, E. J. SHIMANSKI, and K. W. MACFADYEN are with the General Electric Company, Pittsfield, Mass.

The authors are indebted to J. R. Meador and E. L. Raab, General Electric Company, and to C. D. Cook, now at the University of Vermont, for their valuable suggestions and encouragement in carrying out this work. They would also like to thank T. W. Hall for his help in modification and construction of the detection instrument for moisture measurement.

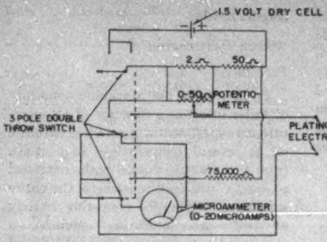

Fig. 1 (left). Circuit diagram for electrometric water method

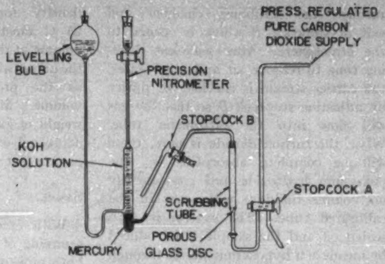

Fig. 3 (right). Apparatus for dissolved gas content of liquids

Procedure

A suitable solvent is introduced into the titration chamber and the end point approached by addition of iodine reagent to neutralize the moisture present in the solvent. While water is present to react with the iodine-forming hydriodic acid, the anode remains depolarized and the cathode polarized, allowing no flow of current. When all the water has been reacted, the addition of iodine depolarizes the cathode, resulting in a current flow. The end point is reached when this flow of current results in a steady reading on the microammeter. A sample (15 to 25 grams) of oil or other liquid of unknown moisture content is added, and the system resealed. If moisture is present, it will be indicated by a decrease in the current flow and a movement of the microammeter needle toward zero. The iodine reagent is then added from the calibrated burette until a steady reading on the instrument is again obtained. The amount of reagent in milliliters (ml) is recorded as well as its predetermined moisture equivalence. This information is then used in the following equation to give moisture content in parts per million

$$\frac{\text{ml Fischer reagent}\times\text{moisture equivalence (grams per ml)}\times 10^6}{\text{Sample weight (grams)}}=\text{parts per million water}$$

The method has been found reliable and the precision calculated to be within ±2 parts per million. Of particular importance is the fact that little experience is necessary for an operator to obtain accurate and reproducible results.

ANALYSIS FOR AIR AND OTHER GASES

In the past 10 years there has been increasing emphasis upon measurement and control of dissolved gases in various liquids. It has always been recognized that this factor was significant in certain systems such as the lubricating, hydraulic, and fuel systems of high-altitude aircraft where extreme pressure and temperature changes coupled with too large a gas content could cause considerable gassing. A comparatively recent development, however, is an increasing concern over this factor in the electrical industry, at least where liquid dielectrics in apparatus of more complex design are concerned.

A number of analytical methods for measurement of dissolved air in insulating liquids have been in use for some time. The majority of these methods, where accuracy and precision are desired, are built around very elaborate high-vacuum apparatus. In most cases the determination involves either absorbing measured quantities of air into a completely degassed oil or measuring the quantity of air evolved when an aerated oil is exposed to a vacuum system.[6] The difficulties encountered in maintaining an absolutely airtight system, calibrating the entire volume of the system, and ensuring equilibrium, make these methods very tedious, expensive, and not as reliable as the method which is used by the authors and hereafter described.

Paralleling the work on moisture already described, and utilizing the same sampling techniques, a method has been developed for determining air and many other gases in liquids such as transformer oil. Fairly inexpensive equipment is involved and the method allows rapid determinations using a small amount (10 ml.) of sample. Results obtained can be expressed either on a volume per-cent basis or on a weight per weight basis and a precision of ±0.2 parts per million by weight is attainable. The operating principle involves the use of a carrier gas which displaces the gas to be determined and is itself subsequently absorbed chemically, allowing volumetric measurement of the displaced gas.

Apparatus

The apparatus is shown in Fig. 3 and consists of an all-glass system which is sealed and into which is piped a supply of pure carbon dioxide. A scrubbing chamber fitted with a porous glass disk for dispersion of the carrier gas is the means by which the rapid displacement takes place. A factory-calibrated nitrometer, commonly used for the microdetermination of nitrogen evolved in organic combustion methods and containing a strong solution of potassium hydroxide, is utilized to collect and measure the gas carried over by the carbon dioxide. The carrier gas in turn reacts chemically with the hydroxide solution and is completely reabsorbed from the gas stream.

Procedure

Stopcock *A* in Fig. 3 is adjusted so that the carbon dioxide is allowed to flow

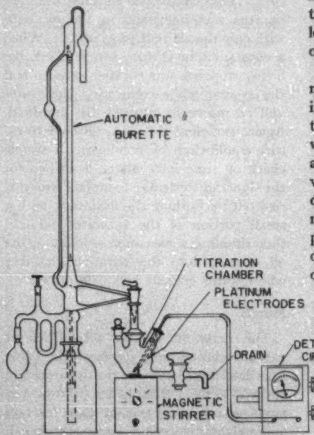

Fig. 2. Apparatus for electrometric water determination

through the scrubbing chamber and exit at stopcock *B* which is opened to the atmosphere. After sufficient flushing time to remove air and other gases, the carrier stream is checked for purity by adjusting stopcock *B* so that the gas will flow into the nitrometer tube. When the carbon dioxide is pure, there will be complete absorption by the potassium hydroxide and consequently no volume build-up will occur in the calibrated tube. The system is then sealed off and the sample is introduced by means of a hypodermic needle through a rubber stopper at the top of the scrubbing tube. The carrier gas is then flowed through the oil causing displacement of the dissolved gas by saturating the oil with the highly soluble carbon dioxide. This displaced gas is collected in the calibrated tube and its volume read by means of a levelling bulb which equalizes the pressure inside the sealed tube with the atmosphere.

The temperature, barometric pressure, volume of gas collected, and volume or weight of oil used are recorded, and the amount of dissolved gas calculated according to the needs of the particular investigation, i.e., either as a weight or volume relationship. Correction factors are supplied with each calibrated burette and should be included in the over-all calculation. The initial portion of the calculation involves expressing the collected gas as a volume at some predesignated standard condition. Conditions chosen in this investigation were 760 millimeters (mm) of mercury for pressure and 25 degrees centigrade (C) for temperature. For this expression the calculation becomes

$$\frac{Va\times Pa\times Ts}{Ps\times Ta}=Vs$$

where

Va = actual volume of gas collected in cubic centimeters
Pa = atmospheric pressure in mm mercury, barometer
Ps = standard reference pressure in mm mercury, 760
Ta = temperature, degrees Kelvin, at which Va was measured
Ts = standard reference temperature, degrees Kelvin, 298
Vs = volume of gas corrected to standard reference conditions

This gives the volume of gas based on a standard reference and allows a realistic comparison of results. If the corrected gas volume obtained is divided by the oil sample volume at 25 C and multiplied by 100, the result is the gas content in volume per cent.

For conversion to weight units the density for the particular gas at 25 C must be known and when the volume at that temperature is calculated, the actual weight of gas is obtained simply as the product of the density and volume. Multiplication of this gram weight of gas by 10^6 and division by the actual oil weight in grams will give the gas content in parts per million.

SAMPLING

With exceptions noted in procedure, sampling of all systems under study for both moisture and gas content measurements was carried out by means of a standard glass medical syringe (10 to 30 ml) equipped with suitable valve attachments, needles, and adapters to meet particular needs. This technique has allowed accurate oil sampling from various systems under equilibrium, both pressurized and evacuated at relatively remote locations, and has allowed convenient transport and storage of these samples in preparation for analysis with no compositional alteration. Where necessary, samples were maintained under exact physical conditions existing in a system in question. In sample transfer to the syringe, especially in liquid systems highly saturated with gas, care was taken to avoid separation of gas during transfer. After sampling was completed, if such separation occurred in subsequent handling, separated gas trapped in the syringe was accurately accounted for in final analysis. Syringe transparency has an advantage in that ready examination of the sample can be made at any handling stage to observe oil condition and avoid error. In cases in which light effects were potentially significant, care was taken to shield the syringe properly. In sampling and analysis for moisture content, it was desirable to allow the internal surfaces of the syringe to come as close to equilibrium as possible with the moisture in the liquid under study. This was accomplished by conditioning the syringe prior to sampling in an atmosphere of proper humidity or, more conveniently, by repeated rinsing of the syringe with the liquid in question. Generally speaking, it is important to recognize the previous history of the samplers before use, particularly when repeated use is involved in studies covering wide moisture variations. It is significant that these same techniques are applicable not only to accurate moisture and gas analysis in oil, but also to critical laboratory study of related transient oil quality factors such as dielectric strength, resistivity, and power factor.

Experimental

WATER SATURATION

Procedure

To determine the maximum solubility of water in oil as a function of temperature, an experiment was set up to saturate oil at several temperatures in a range from 12 to 80 C. An oil bath controlled to ±0.1 C was used to immerse the entire saturation apparatus consisting mainly of two water-saturating columns, a glass wool entrainment filter and an oil reservoir, all in series. Each vessel in this train was fitted with a porous glass dispersion disk through which air was passed at a steady rate. Sampling was accomplished by means of a medical syringe which was preheated or cooled in the same bath so as to minimize temperature change in transfer to the titration chamber.

The time required to insure equilibrium was established by sampling after several widely different time intervals. In all cases, the maximum water content was reached before 8 hours of air flow at the prescribed flow rate. Time intervals of 24, 32, 48, and 72 hours were checked and no increase in water content observed. A 24-hour minimum period was utilized for establishing the equilibrium conditions at various temperatures for the dynamic system described. An independent check for maximum water content was made on a nonflowing system to ensure that the results were not a function of the method of saturating. This all-glass apparatus consisted of an oil and a water reservoir connected through a vented glass manifold and provided with an oil drainage cock. For this static system, the apparatus was immersed in the oil bath with only the air vent protruding. When a constant temperature was reached, the 2-way stopcock was rotated so as to seal the system while connecting the water and oil reservoirs through the manifold. Again, sufficient time was allowed to insure equilibrium by conducting a simple check on time intervals as described for the dynamic system. Sampling was carried out by flushing the draincock with a small portion of the saturated oil and then draining a measured amount of the oil directly into the titration chamber where water content was determined.

Results

The maximum water solubilities at various temperatures are shown in Table I, as determined by both the dynamic and static systems. Results are expressed in parts per million by weight, mole fraction and weight per cent(%) of water in oil.

Vol.
Pt. 1

Table I. Maximum Water Solubilities in Transformer Oil

Temperature, C±0.1C	Parts per Million	Mole Fraction†	Weight, %
12	30	0.00046	0.0030
20	44	0.00068	0.0044
30	67	0.00104	0.0067
40	101	0.00156	0.0101
40.5*	103	0.00160	0.0103
50*	149	0.00231	0.0149
60	213	0.00331	0.0213
60*	215	0.00333	0.0215
80*	411	0.00632	0.0411

* These results determined under static conditions.

† Mole fraction is a quotient obtained by dividing the number of moles if water present by the number of moles of oil and water combined.

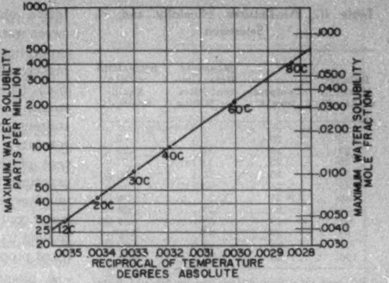

Fig. 5. Water content of transformer oil at saturation as a log function of temperature

These results are plotted in Fig. 4 on rectangular co-ordinate paper and in Fig. 5 on semilog paper showing a linear relationship between log of the solubility and the reciprocal of the absolute temperature.

Discussion

As previously stated, the primary objective of this systematic investigation of moisture is its application to broader study of insulating liquid behavior. Limited consideration is given to theoretical explanation for the observed relationships since this has been the subject of previous exhaustive and authoritative study.[7–9] The quantitative behavior of moisture in oil as observed in this work, although exhibiting some deviation from strict vapor pressure considerations, is generally in accordance with classic laws governing behavior of dilute solutions (i.e., Raoult's and Henry's laws). Although originating in a completely independent investigation, the findings in these experiments agree with those of Black, Joris, and Taylor,[7] demonstrating similar moisture solubility relationships for various pure liquid hydrocarbons. As is indicated in reference 7, such deviations as were encountered can be expected for specific systems of the type in question, i.e., in dilute solutions in which the components in solution exhibit wide differences in internal pressures, polarity, molecular structure, and degree of association in the liquid state.

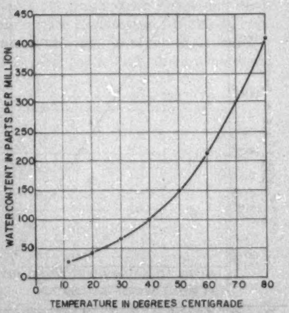

Fig. 4. Water content of transformer oil at saturation as a function of temperature

The work confirmed the fact that as the chemical constitution of hydrocarbon-type liquids change, water solubility in these liquids may also change. However, the characteristic principles cited for transformer oil widely apply to similar organic liquids in establishing moisture saturation-temperature curves and in defining moisture equilibrium as a function of humidity. In this general study, characteristic conformity has been shown not only for conventional transformer oil, a highly complex mixture of hydrocarbons, but also for related liquids of higher or lower aromatic, paraffinic, or unsaturates content, as well as of other differences in molecular structure or composition. This is illustrated in the comparison of the moisture saturation curves for conventional transformer oil with an oil of predominant aromatic composition, and their comparison, in turn, with that of benzene and to published saturation data[10] for cyclohexane, as shown in Fig. 6. It will be noted that all exhibit a linear relationship between the log of solubility and the reciprocal of the absolute temperature. Slopes of the saturation curves vary because of intrinsic compositional differences in the liquids. Characteristic variations of the same type have been observed on transformer oil itself because of differences in natural origin and refining or impurities originating in oxidative or thermal deterioration of a particular oil with use.

Relative Water Saturation

Procedure

The question of water-oil equilibriums for varying air relative humidities was also investigated and the % moisture saturation of oil in equilibrium with moist air was found to agree exactly with the % relative humidity of the air when both are at the same temperature. To express this in another way, it might be said that when oil and moist air are in equilibrium at some given temperature, the ratio of water present in air to the maximum that air will contain at that temperature, is exactly equal to the ratio of water in oil to the maximum water that oil will contain at that temperature. It was important that this phenomenon be studied since there are substances in which water does not absorb according to this rule. Paper and pure cellulose are among such substances in which a nonlinear relationship exists between water absorption and air-relative humidity.

The relative humidity of the air for these experiments was established by use of both static and dynamic methods. In certain cases the oil was placed in a sealed container in which the % of humidity was varied by means of saturated salt solutions. In other instances, a flowing air

* Per-cent saturation values are determined from a knowledge of the 100% or saturated water content for the temperatures given. At 25 C this value is 54 parts per million and at 26 C it is 56 parts per million by reference to Fig. 5.

stream was passed through either a glycerine-water solution or a saturated salt-water solution and then dispersed through the oil. Excellent agreement was achieved between these two methods, indicating, as in the case of the 100% saturation data, that the equilibrium is not dependent upon the method used to attain it.

Results

The results are shown in Table II and plotted in Fig. 7. Although very little information is available on relative saturation at elevated temperatures, it is assumed that this linear relationship between air humidity and % water saturation in oil holds throughout the temperature range of practical interest. A family of curves relating water content of oil with air relative humidity over a practical range of temperatures is shown in Fig. 8.

Discussion

Much of the work and literature relating to moisture in dielectrics recognizes its importance. However, confusion and contradiction exist as to the exact quantitative relationships and correlations between water content and various electrical properties. Much of this is due to preoccupation with attempted correlations based on absolute water content without reference to what a given water content represents in terms of relative saturation. This excludes a novel concept of the authors, well substantiated experimentally, that the state of relative moisture saturation, and not absolute water content per se, is a critical and controlling factor with respect to many electrical properties.

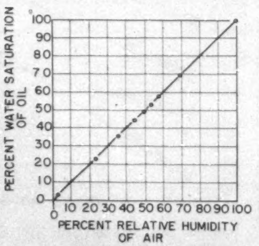

Fig. 7. Relative water saturation of transformer oil as a function of air humidity at equilibrium

A practical illustration of the significance of the relative moisture picture is given by reference to parallel work relating specific electrical properties to relative water saturation. An article on a continuous-flow moisture detector[11] deals in detail with resistance, power factor, and capacitance measurements as a function of and as a means for detecting the water content of a flowing oil system. A typical picture of the relationship between the insulation resistance and the relative water saturation over a fairly wide temperature range is given in Fig. 9. These results, determined by the authors in the course of the fundamental studies on moisture equilibriums and coupled with other findings presented in this paper, provide a foundation for relating many other dielectric phenomena to the relative amounts of water present in a liquid system. If these fundamental relationships are properly recognized and utilized, a more profitable approach can be made to quantitative interpretation of dielectric phenomena.

AIR SATURATION

Procedure

Similar experimentation was carried out to determine maximum air solubilities in transformer oil at various temperatures and pressures. A constant temperature bath and a simple apparatus consisting of a glass vessel with an air vent and containing about 500 cubic centimeters of oil was used. Samples were drawn into a syringe which was preheated for determinations at elevated temperature and then transferred to the analytical apparatus shown in Fig. 3. As in the case of the water saturation study, several time intervals were checked until it was certain that equilibrium had been reached. Temperatures of from 25 C to 120 C were studied. Air saturations of this static oil system, as well as one through which air was passed by means of a porous glass disk, were determined and found to agree, providing that any free air bubbles were allowed to escape.

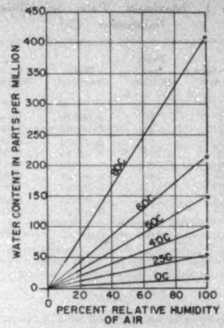

Fig. 8. Water content of transformer oil in equilibrium with moist air for several temperatures

Results

The maximum solubilities of air in transformer oil at atmospheric pressure for temperatures of practical interest are given in Table III. The data, plotted in Fig. 10, show that, at fixed pressure, the solubility of air is directly proportional to the temperature at which it was saturated.

Although a volume % expression is a rather convenient means for picturing the gas condition of a liquid insulator, and is useful for various engineering calculations, it can be misleading if inadequately defined. As one means of expressing gas solubility in the present report, the fol-

60	736	10.57	142.8
75	736	10.81	146.2
120	736	11.48	155.2

* The oils were saturated at the prevailing barometric pressure which ranged from 727 to 745 mm, and then corrected to 736 mm by reference to Fig. 11.

lowing conditions were chosen for reference: 25 C for oil temperatue; 25 C, 760 mm for gas temperature and pressure. By such definition, therefore, gas solubility as volume per cent is calculated in accordance with the following expression

$$\frac{\text{Gas volume at 25 C, 760 mm}\times 100}{\text{Oil volume at 25 C}} = \text{volume \%}$$

Standardized use and consistent adherence to such a point of reference is highly desirable. In comparison to these defined conditions, selection of different reference conditions of temperature and pressure obviously give rise to apparent different volume relationships between gas and oil which are unreal in the sense that they rest in the method of calculation only. To minimize the possibility of ambiguity, another expression for gas content is suggested. This involves the conversion of gas content of oil to a weight per weight relationship as expressed in parts per million. These units provide an advantage in that they represent a clear-cut measure of solubility independent of volume change. To say that 1,000,000 grams of oil at 75 C contains 146 grams of air in solution needs no further clarification. If this is compared with the figure for 25 C, which is 135 parts per million, there is no doubt about the increase of solubility with temperature.

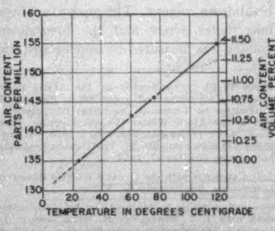

Fig. 10. Air content of transformer oil as a function of temperature

The effect of pressure change on the air content of oil was determined in a separate experiment in which degassed oil was allowed to come to equilibrium with air at pressure levels ranging between 1 mm and 1,000 mm of mercury. This establishes the direct relationship between air content and pressure and also provides a means of correction for barometric change while reaching equilibrium. This curve is in Fig. 11 and can be assumed to hold for pressures up to several atmospheres. Similar linear relationships have been demonstrated for other gases.

In addition to air solubility, a brief study was made of the solution in oil of the individual major components of air, nitrogen, and oxygen. The maximum solubilities of each were determined at 25 C when present as the only dissolved gas component in a previously degassed oil sample. This showed oxygen to be more highly soluble than nitrogen in transformer oil, and led to the investigation of their solubilities as components of air in equilibrium with oil. Although nitrogen comprises 78% by volume of the atmosphere and oxygen 21%, it was found that in oil only 70% of the gas was nitrogen while 30% was oxygen. These data are shown in Table IV. The oxygen enrichment in oil solution is due to the greater solubility of oxygen in oil as also shown in Table IV. It should be noted too that, on a weight basis, oxygen constitutes 40% of air dissolved in transformer oil.

Conclusions

1. Improved analytical sampling techniques and apparatus have been developed and usefully applied to measurement, control, and fundamental study of moisture and gas in transformer oil and related liquids.

2. Fundamental temperature and humidity relationships governing moisture solubility in transformer oil have been established and found in agreement with basic laws governing dilute solution. Data show that the log of the solubility of water in oil and similar organic liquids is directly proportional to the reciprocal of the absolute temperature and that it increases with temperature. This saturation plot provides a useful means of accurately extrapolating limited data to obtain saturation data over the full practical range of interest.

3. Saturation characteristics of these liquids, while conforming to fundamental solubility relationships, show variation attributable to intrinsic differences in individual liquid properties.

4. Relative moisture saturation of transformer oil and various similar liquids has been found to be linearly related to the relative humidity of the atmosphere with which equilibrium was established.

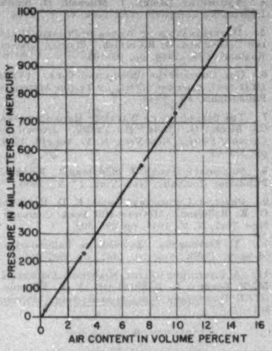

Fig. 11. Air content of transformer oil as a function of pressure

5. Relative moisture saturation, rather than absolute moisture content per se, is suggested as a controlling factor in quantitative correlation of water and many electrical properties of dielectrics.

6. The solubility of air and its major components in transformer oil have been defined for various temperatures and pressures of practical interest.

7. It is shown that air solubility in transformer oil increases slightly with temperature between the limits of 25 and 120 C, and that air undergoes a compositional change in oil solution because of inherent differences in solubility of its major components.

8. The air content of oil at saturation varies linearly with the pressure at which equilibrium is established.

Discussion

Frank C. Doble (Doble Engineering Company, Belmont, Mass.): We are pleased that the authors understand the concept "that the state of relative moisture saturation, and not absolute water content per se, is a critical and controlling factor with respect to many electrical properties." This concept led me to present before the National Research Council Insulation Conference on November 2, 1939, a paper entitled "Low Loss and High Loss Water in Oil." The terms "low loss" and "high loss water" were suggested for the purpose of describing the phenomena upon which this concept is based.

One of the oils studied by the authors, identified as an aromatic oil, has markedly different water saturation characteristics from that of the transformer oil. Since natural aromatics play an important part in determining the characteristics of transformer oil, we should like to ask whether the aromatic oil is of the transformer oil type and what percentage of aromatics it contained; also if the authors have studied the effect of relatively small changes in aromatic content of transformer oil such as occur when a distillate is subjected to different amounts of refinement.

R. B. Kaufman, E. J. Shimanski, and K. W. MacFadyen: The authors are gratified with Mr. Doble's concurrence on the significance of relative moisture saturation in liquid dielectrics. His implication, however, that this concept was clearly recognized as early as 1939 is rather surprising in view of the industrywide need for, and persistent efforts toward, improved standardization and refinement of methods for more accurately determining the moisture content and dielectric liquids. As is pointed out in the paper, the clear delineation of moisture and its effects in the diminutive solubility ranges and homogeneous systems with which we are concerned required the most careful techniques of sampling and analysis. The many contradictions in published literature and lack of attention to the exact parameters which must be used in definition of moisture solubility and its related effects in dielectrics are difficult to reconcile with Mr. Doble's viewpoint. We have been unable to obtain a copy of his unpublished 1939 paper, to compare his concept with ours of low-loss and high-loss water in oil.

The aromatic oil referred to by the authors was a synthetic blend of essentially complete aromatic composition which was cited simply as a further illustration of a relationship between composition and moisture solubility in hydrocarbon-type liquids. It was not a transformer-type oil in the classical sense to which Mr. Doble refers. Although we have not studied exhaustively the moisture saturation characteristics of every commercial transformer oil, we do know that severe alteration in the aromatics content of those oils with which we are most familiar significantly affects their moisture solubility characteristics. Further, we recognize that this is not the only compositional variation influencing the moisture saturation characteristics of natural oils of this type.

Some Electrical and Thermal Characteristics of Helium and Sulfur-Hexafluoride Mixtures

J. D. COBINE
MEMBER AIEE

Synopsis: The results are presented of a study of some of the electrical and thermal properties of mixtures of helium and sulfur-hexafluoride which are compared with the pure gases: air, hydrogen, helium, and sulfur-hexafluoride. It is shown that the addition of relatively small amounts of sulfur-hexafluoride to helium will result in an electric strength greater than that of air and of hydrogen. The thermal properties of such mixtures are nearly as good as hydrogen. The mixture is attractive as a cooling and insulating medium for both static and rotating machines. Such a mixture is very safe whereas hydrogen presents an explosive hazard. Permeation losses through metal containers are much less than for hydrogen.

HYDROGEN is often used as a gaseous cooling medium in electric machines[1,2,3] where high heat-transfer and low windage power losses are desired. This gas has some disadvantages, among which may be noted the following. Its electrical breakdown strength is about 65 per cent that of air over a considerable range of pressures. There is a certain amount of hazard involved caused by the possibility of air mixing with the hydrogen, either inside the machine or in pockets outside. The permeation rate of hydrogen from metal containers is greater than for other gases.[4]

Helium has nearly as good thermal properties as hydrogen; its loss through metals is very low compared to hydrogen, but its electric strength is very low. It is now well known that the presence of small amounts of electronegative gases tends to raise the breakdown voltage of gases.[5] However, there appears to have been no study of the possibility of developing a gaseous mixture having both high electric strength and good thermal properties. The following summarizes the results of a study of the electrical and thermal characteristics of mixtures of helium and the electronegative gas sulfur-hexafluoride.

Experimental Results

All electrical and thermal measurements were made in a 9-inch bell jar. The base plate and internal arrangement are shown in Fig. 1. All spark breakdown voltages were for 60-cycle-per-second power and were measured for 1-inch-diameter hemispheres of stainless steel which had a 1/8-inch radius of curvature at the back edges. To reduce the erosion of the surfaces of the spheres to a minimum, a thyratron-controlled relay was used to remove the voltage upon the flow of breakdown current. The gap was set by a micrometer screw and the breakdown voltage was measured by an electrostatic

Paper 55-10, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted August 25, 1954; made available for printing October 27, 1954.

J. D. Cobine is with the General Electric Research Laboratory, Schenectady, N. Y.

The author wishes to acknowledge helpful discussions with J. K. Bragg, M. H. Hebb, and F. J. Norton. The thyratron-controlled relay described in the paper was developed by S. Reynolds of this laboratory.

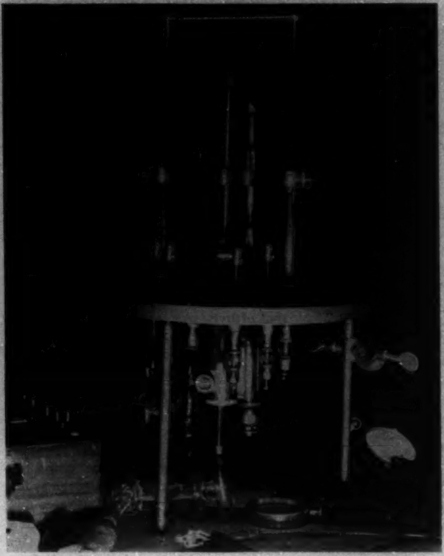

Fig. 1 (left). Experimental apparatus

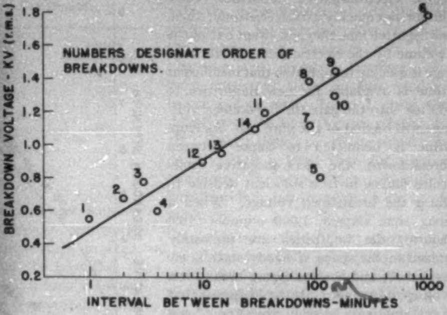

Fig. 2 (above). Effect of interval between breakdown on helium with small amount of SF_6 impurity (74.6 centimeters Hg)

voltmeter (calibrated in rms voltage). The gases, air, hydrogen, and helium were admitted to the system through a dry-ice–acetone trap. The sulfur-hexafluoride was chemically pure and showed no trace of impurities when examined by mass spectrograph, while the helium used was of welding grade. The voltage was increased slowly so that at least 15 seconds were required to reach breakdown. An interval of at least 1 minute elapsed between successive breakdowns. The first spark breakdown data were taken with air so that the equipment could be tested by comparing results with published data.

While taking exploratory data, it was found that once sulfur-hexafluoride had been used in the bell jar, it was impossible to obtain consistent data with helium even after repeated flushings with pure helium. Once contaminated, the breakdown voltage obtained with helium depended markedly on the time permitted to elapse between breakdowns. The data presented in Fig. 2 show that there is quite a systematic dependence of breakdown voltage of helium on the time permitted to elapse between breakdowns. Point 6, at 1,000 minutes, represents the upper limit of breakdown voltage and point 1, taken 1 minute aftere a preceding breakdown, is approximately the lower limit. This lower limit is equal to the value obtained for helium before any sulfur-hexafluoride was used in the system. The effect was certainly caused by residual amounts of sulfur-hexafluoride in the system. The flushing alone would have reduced the gaseous proportion of sulfur-hexafluoride to an extremely small value; however, large surface areas are present upon which many layers of gaseous impurities are adsorbed. Thus, no realistic estimate of the amount of sulfur-hexafluoride present could be made.

The following hypothesis appears to offer a reasonable explanation. When a breakdown takes place in a gas containing

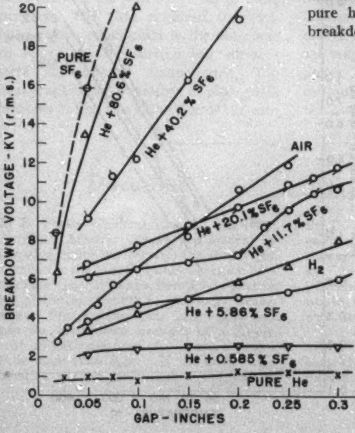

Fig. 3 (left). Spark breakdown voltages for air, He, H_2, SF_6, and mixtures of He+SF_6 for 1-inch-diameter hemispheres. (74.6 centimeters Hg, 29.5 degrees centigrade, 60-cycle voltage)

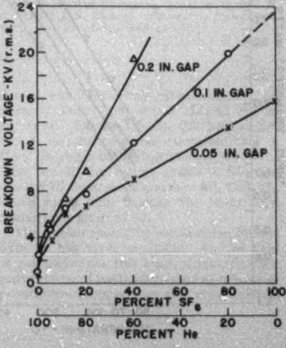

Fig. 4 (right). Spark breakdown voltage for SF_6+He mixtures. Parameter = gap between 1-inch-diameter hemispheres (74.6 centimeters Hg, 29.5 degrees centigrade) some electronegative impurities, these impurities quickly attach electrons; then, as negative ions they are swept out of the volume by the electric field. If the voltage is quickly reapplied so that insufficient time is available for new impurities to diffuse into the gap, the breakdown voltage will be that of the pure gas. As more time is permitted to elapse between breakdowns, the electronegative molecules diffuse in to a sufficient density to raise the breakdown voltage. When a long time elapses, 1,000 minutes (16.6 hours), the impurities are uniformly mixed in the space, a steady state is established, and the maximum breakdown voltage is observed. It would appear that a systematic variation in spark breakdown such as this represents a good way to detect the presence of very small amounts of electronegative gases mixed in other gases. The procedure followed in taking the final data consisted in filling the system to nearly atmospheric pressure and pumping to 200 microns for 5 cycles. In at least 3 cycles, a low-pressure glow discharge of about 10 minutes' duration was established in the new gas. This procedure removed residual impurities from all surfaces to a suitable minimum value.

The 60-cycles-per-second spark breakdown voltages for air, hydrogen, helium, sulfur-hexafluoride, and mixtures of the last two are shown in Fig. 3. The volumetric proportions of the two gases are indicated as percentages. A total pressure of 74.6 centimeters Hg was used throughout the study. The values plotted represent the average of ten breakdowns. The rms deviations from the average value were generally from 1 to 5 per cent, being greatest for the shortest gaps. The breakdown curve for air is slightly lower than published values, probably cause by the fact that the electrodes were not true spheres. However, the ratio of the breakdown voltage of hydrogen to that of air is equal to the published values, namely, about 65 per cent. These curves show the marked effect of even small amounts of sulfur-hexafluoride in increasing the breakdown strength of helium. The data of Fig. 3 are replotted in Fig. 4 to bring out directly the effect of the amount of sulfur-hexafluoride mixed with the helium. As the gap length approaches the radius of the electrodes, the electric field becomes more distorted. For this reason, comparative values are given for only the shorter gap lengths when the field is more nearly uniform. The values of breakdown voltage for the helium–sulfur-hexafluoride mixtures are shown in Fig. 5 relative to that of hydrogen and of air for two gap lengths. The marked gain in electric strength of helium with small additions of sulfur-hexafluoride over both air and hydrogen is brought out quite well by this figure. This gain is especially great for small spacings, as the 0.05-inch-gap data show.

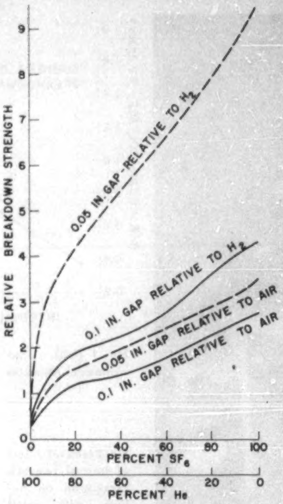

Fig. 5. Relative breakdown strength of mixtures of $He+SF_6$

The total heat loss from structures immersed in a gas is dependent on the geometry and orientation of the surfaces and is usually quite complex. It was felt that a determination of the heat transfer for the several gases relative to air from measurements made in the same simple structure would be instructive. The relative heat-transfer data thus obtained would be useful in estimating the heat losses from other structures where the loss rate in air is known. For the present study, the term "heat transfer" is taken to mean the electric power input to a helix

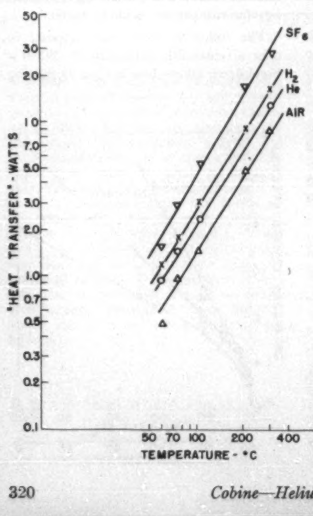

Fig. 6 (left). Heat transfer by free convection and radiation for pure gases, (power in watts required to maintain temperature T at center of wire helix, ambient = 26 degrees centigrade, pressure = 74.6 centimeters Hg)

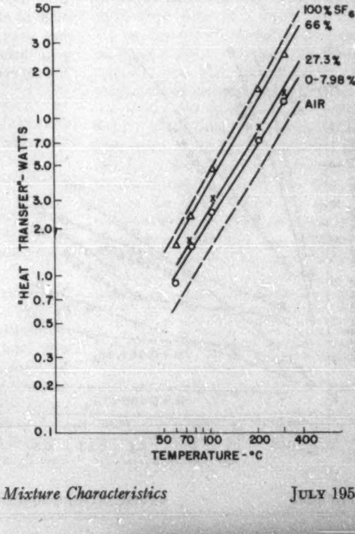

Fig. 7 (right). Heat transfer for mixtures of SF_6+He (ambient = 26 degrees centigrade, pressure = 74.6 centimeters Hg)

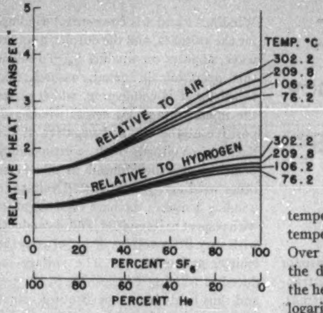

Fig. 8. Relative heat transfer of He+SF$_6$ mixtures

of resistance wire at a given wire temperature. This includes the combined action of free convection in the gas and radiation as well as a small conduction loss through the end leads.

A helix of 0.015-inch-diameter nichrome wire wound on a 5/16-inch mandrel, as shown in Fig. 1, had a platinum-rhodium thermocouple spot-welded at the center. The length of the helix was 15/16 inch, with a pitch of 0.0445 inch. The cold resistance, including that of the contacts, was 5.7 ohms. The length of wire is quite long so that the heat loss of the leads is small relative to the total loss. The power input necessary to maintain a constant temperature of the wire at the center of the helix will be called the heat transfer.

As shown in Fig. 1, the helix is in a large bell jar with a heavy stainless-steel plate; consequently, the heat loss is all to these surfaces. The time required to reach temperature equilibrium in the helix was so short that the surrounding surfaces were at constant temperature. The heat transfer for a number of pure gases is shown in Fig. 6 as a function of the wire temperature, at the constant ambient temperature of 26 degrees centigrade. Over the range of temperature involved, the data indicate that the logarithm of the heat transfer is a linear function of the logarithm of the wire temperature. The values were quite reproducible except at the lowest temperature, 60.4 degrees centigrade, where the measurements were somewhat erratic.

Table I. Gas Densities

Gas	Density Relative to Air
H_2	0.0695
He	0.138
Air	1.0
SF_6	5.03

The heat-transfer characteristics of mixtures of helium and sulfur-hexafluoride are shown in Fig. 7. The relations for air and pure sulfur-hexafluoride are included for comparison. In Fig. 8, the heat-transfer of the He+SF$_6$ mixture is shown relative to air and hydrogen as functions of the per-cent sulfur-hexafluoride. The latter figure shows that the heat transfer of the mixture is always greater than that for air; while it is never less than 80 per cent of that for hydrogen it is better than hydrogen for percentages of sulfur-hexafluoride greater than about 30 per cent.

Discussion

Some of the factors involved in a rotating device, such as an alternator or a gyro, are different from those involved in a static device, such as a transformer or ballast reactor. In a large high-speed machine, the power loss caused by windage may be as much as one-half the total power loss. A cooling and insulating medium should be such as to minimize this loss as much as possible, consistent with the desired electrical and thermal properties. In turbulent flow of gases, the power loss increases with both viscosity and density. However, the most important factor in this windage loss is gas density. Table I gives the densities of the several gases relative to air. Since drag is proportional to density, it is evident that, for roating machines, the percentage of sulfur-hexafluoride in helium must be kept to a minimum.

In addition to the inherent safety in the use of the chemically inert gases, helium, and sulfur-hexafluoride, the mixture has the advantage of being adaptable to the use of a simple halogen leak detector.[6] Permeation loss of both gases through metals is immeasurably low; however loss of helium by permeation does take place through glass, silica, rubbers, and plastics.[4] The combination of an inert gas such as helium with an inert electronegative gas such as sulfur-hexafluoride to produce a gas whose electrical and thermal properties can be tailored to a particular application should have many applications.

Discussion

R. E. Plump (General Electric Company, Pittsfield, Mass.): There are several interesting points for comment in this paper. The first is the fact that once again we have evidence that SF$_6$ has a beneficial effect on the dielectric strength of relatively weaker gases. Fig. 4 shows that in the 0.05-inch gap the breakdown strength of a 20-per-cent SF$_6$–80 per-cent He mixture was a little more than 6 kv. If the linear combination of each gas is made (i.e., assuming direct proportionality) such as, by the equation $kv = x(DS_{SF_6}) + (1-x)\ (DS_{He})$ in which x is the fraction of SF$_6$ present, and the DS's are the dielectric strengths of each gas alone in the gap, then the strength of the mixture should have been only about 4 kv. In other words, the mixture had a 50-per-cent higher dielectric strength than would have been obtained proportionally from each component in the mixture.

The fact that heat transfer with SF$_6$ is higher than with either H$_2$ or He may be somewhat surprising when SF$_6$ is known to have a slower rate of diffusion. However, it also has interatomic vibrations (i.e., an infrared absorption) which H$_2$ and He do not have. Further, the specific heat of SF$_6$ is only one-eighth to one-twentieth that of He or H$_2$ respectively, but in a given volume there are 36 times more grams of SF$_6$ and He and 73 times more grams of SF$_6$ than H$_2$, which more than balance the lower heat content per gram of SF$_6$.

The author should be commended for the data he has made available. In the field of gas dielectrics this kind of investigation proves to be of particular value as industrial possibilities become more and more feasible.

A Switching Transistor D-C to A-C Converter Having an Output Frequency Proportional to the D-C Input Voltage

G. H. ROYER
ASSOCIATE MEMBER AIEE

THE combination of transistors and transformers constructed of square hysteresis loop material has produced much useful circuitry outside of the realm of magnetic amplifiers per se. In this paper a highly efficient and extremely precise converter for transforming direct to alternating current, yielding a square-wave output whose frequency is proportional to the d-c input voltage, will be described. From among the many uses of this converter, the following applications will be discussed: 1. a transducer for telemetering systems, and 2. an integrator which has found application as an analogue to digital converter.

Transistor Switches

The use of junction transistors as controlled switches has been described previously,[1,2] but a few of the main points will be reviewed here. Fig. 1(A) shows the collector characteristics of a PNP transistor in the common emitter connection, as illustrated in Fig. 1(B). For the load line shown, two operating points are of interest: cutoff, point *F*, where the transistor sustains almost the entire supply voltage *E* with very little leakage current and conduction, point *S*, where a large enough base drive is applied to saturate the transistor and reduce the voltage drop V_{ce} to its lowest possible value. Cutoff occurs when the base voltage is slightly positive giving a small positive current in the base. Typical values of cutoff current for small 200-megawatt *2N74* fused junction transistors are from 5 to 50 microamperes at a supply voltage of 45 volts and a base voltage of +0.5 to 5 volts. In the conducting state voltage drops of 0.1 to 0.5 volt are obtained with 50 to 150 milliamperes' load current; however, the amount of base current required to saturate the transistor depends greatly on the gain of the transistor and the amount of load current. The effective transistor impedance can be changed from over a megohm at cutoff to a few ohms at saturation by control of the base voltage and current; this can be compared to the operation of a relay where the emitter-collector circuit is analogous to the contacts and the base-emitter circuit is analogous to the energizing coil. For the purpose of this paper, the above information can be summarized by two simple rules. The PNP transistor switch will conduct if the base is negative with respect to either emitter or collector and will block if the base is positive with respect to both emitter and collector.

Basic Circuit of Converter

Two junction transistors used as controlled switches and a transformer with a square hysteresis loop core material form the basic circuit of the voltage-to-frequency converter illustrated in Fig. 2. A typical ϕ-i curve for such a transformer constructed of Hipernik V is also illustrated in Fig. 3. The two transistors alternately conduct and switch the input voltage V_{in} across windings 2 and 3, causing the flux in the core to be cycled between positive and negative saturation.

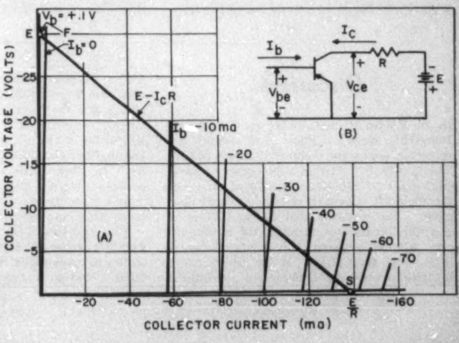

Fig. 1. (A) Collector characteristics of PNP transistor. (B) Common emitter connection showing load circuit

Windings 1 and 4 act as control windings for the switches, and the output, a square wave, appears on winding 5. To follow this operation in detail, assume that transistor *A* is conducting, which places the input voltage V_{in} across winding 2, positive at the top and negative at the bottom. Voltages with corresponding polarities will be induced in all of the other windings. This induced voltage in winding 1 makes the base of *A* negative with respect to its emitter, and *A* conducts with very little voltage drop between the emitter and collector. The voltage induced in winding 4 is positive at the top and thus holds transistor *B* cutoff, since its base is positive with respect to both the emitter and collector. Transistor *A* continues to conduct until the flux reaches the saturation value $+\phi_m$.

Upon saturation, several effects occur simultaneously; the current rises sharply to a value determined by the base drive of the transistor, the induced voltage in the transformer windings disappears, and the voltage across the transistor rises. The loss of the base drive causes transistor *A* to open the circuit to winding 2 and causes the flux to fall back slightly to the retentivity value which induces a small voltage of the opposite polarity in the windings. This places a negative voltage on the base of the transistor *B* which begins to conduct, causing the flux to decrease still further, and the cycle is rapidly reversed until transistor *B* is conducting heavily and transistor *A* is open. The input voltage is now connected across winding 3, positive at the bottom and negative at the top. The flux decreases linearly until the core saturates in the opposite direction and a similar reversal takes place to complete the cycle.

The output voltage is a square wave where the duration of each half-cycle is

determined by the time necessary for the flux in the core to change from $-\phi_m$ to $+\phi_m$. The frequency of these square waves can be related to the parameters of the core and the input voltage. If N_2 designates the number of turns on each one of the two main windings 2 and 3 and the voltage drop across the transistors and winding resistance is assumed to be negligible, the input voltage V_{in} is applied directly across a winding of N_2 turns

$$V_{in}=N_2\frac{d\phi}{dt}$$

Integrating this relation over one half-cycle

$$\int_0^{\frac{1}{2f}} V_{in}dt=\int_{-\phi_m}^{\phi_m} N_2 d\phi$$

Therefore

$$f=\frac{V_{in}}{4N_2\phi_m}$$

From this expression it is evident that, for a given transformer, the output frequency is proportional to the d-c input voltage. Such a characteristic is well suited for telemetering applications where the output frequency transmitted between a measuring point and a metering station is an indication of a voltage measurand at the originating point. As the transistors are used as switches or on-off devices, and their conduction resistance is only a few ohms, their characteristics do not materially affect the proportionality. The saturation flux of Hipernik V changes about 0.07 per cent per degree centigrade and, thus, the constant of proportionality will vary correspondingly with temperature.

Bias Circuit

To insure good switching operation, the minimum voltage at the transistor bases should be about 1 volt. If a 20-to-1 operating range is desired, the voltage induced would be 20 volts at the upper end of the range. The switching current in the bases would vary over a much greater than 20-to-1 range because of the nonlinear characteristic of the emitter-base diode. Consequently, excessive heating or burn-out of the transistor could occur at high currents and, if the range were extended at the low end, improper or no switching would occur at low currents.

To maintain a more satisfactory base drive over a wide range of input voltages, a current bias may be used in the base circuit, as shown in Fig. 4. To explain the operation of this circuit, E_{bias} is assumed to be much greater than the voltages induced in windings 1 or 4, so that the bias circuit effectively acts as a constant-current source of magnitude E_{bias}/R_{bias}. It is also assumed that, initially, all of this bias current is flowing through the base of transistor A. A then conducts and connects the source V_{in} to winding 2 which thereby induces voltages of the polarities shown in 1 and 4 and, e.g., with a magnitude of perhaps 1 volt. The voltage applied to the base of transistor B, V_{bB}, is equal to the sum of the voltages induced in windings 1 and 4 minus the base voltage of A, V_{bA}. A typical value for the drop across the conducting transistor A might be 1/2 volt so that the value of V_{bB}, in this example, would be $V_{bB}=1+1-0.5=1.5$, with the base positive with respect to the emitter and, hence, the base of B is cutoff and the entire bias current must be flowing through A as was originally postulated. The values of the voltage drop V_{bA} and the voltage induced in winding 1 have practically no effect on the magnitude of the bias current I_{bias} since it was assumed that E_{bias} was large. Strictly speaking, $I_{bias}=(E_{bias}+V_1-B_{bA})/R_{bias}$. Thus, in this circuit, the function of the voltages induced in the switching windings is not primarily for producing a current in the base circuit but rather for furnishing a cutoff bias for one or the other of the transistors. But, for this slight change of concept, the over-all circuit operation is identical with that already described. By using this bias circuit with a sufficiently high bias battery, the bias drive can thus be held relatively constant if desired, and this factor is no longer a limitation on the upper value of supply voltage V_{in}. Rather, the upper limit on the input voltage is set by the collector voltage that can be applied to the nonconducting transistor. Since the induced voltage in the transformer adds to the input supply voltage, the rated collector breakdown voltages must be at least twice the input voltage. In addition, the applied voltage must not cause thermal runaway of the nonconducting transistor at elevated temperatures.

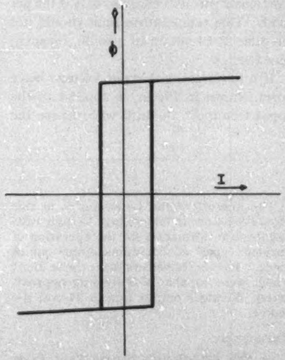

Fig. 3. Typical ϕ-I curve for square hysteresis loop core material

The low limit of V_{in} is set by the fact that, in order for transistor B to be completely cut off, the voltage V_{bB} must be at least 1/10th volt and, therefore, in this example, the sum of the voltage induced in windings 1 and 4 must be at least 1/10th volt higher than the forward drop of transistor A, V_{bA}. Thus, the greater the turns ratio N_1/N_2, the lower the volt-

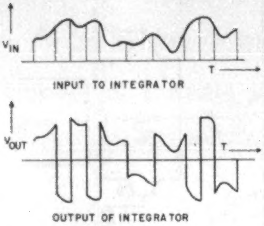

Fig. 5. Voltage wave forms using the converter as an integrator

age limitation on V_{in}. If N_1/N_2 is made too large, the base current referred to winding 2 may be greater than the maximum saturation current, and there will be nothing left over to magnetize the core so that this lower limit cannot be extended indefinitely. As the switching voltage becomes too low to saturate the transistors properly, they can no longer supply the magnetization current for the transformer. Under these conditions, the operation takes place along a minor hysteresis loop. Thus instead of acting as a saturating core, it behaves as a linear inductance in parallel with its distributed capacity. The device then changes its mode of oscillation and operates as a quasi-linear oscillator whose frequency increases as the input voltage decreases. Two precautions must therefore be observed if this device is to be used for instrumentation purposes: The input voltage must not change sign and, furthermore, it should not fall below the critical value at which the mode of oscillation changes. Input voltages of as low as 100 millivolts and up to 40 volts have been applied and, by the proper choice of cores and number of turns on windings 2 and 3, converters have operated at frequencies from one half-cycle per second up to 12 kilocycles.

Since the transistors are operating as switching devices, they will operate over a wide ambient temperature range; the circuit shown has been operated from −60 to +40 degrees centigrade, and to +75 degrees centigrade with selected transistors. Some laboratory models of this converter have operated over an input voltage range of 100 to 1. For a constant core temperature, converters of this configuration have been operated over a 20-to-1 range with a frequency output proportional to the input voltage to within a deviation of only 0.2 per cent of full-range frequency.

Applications

The circuit described in the previous section is accurate enough to warrant application of the device as a telemetering transmitter. The output square wave can be transmitted directly, or filtered, if elimination of the higher harmonics is desired. While the converter may be loaded to deliver as much as 1 watt of output power, the voltage-to-frequency linearity is sacrificed so that an output buffer stage may be necessary to maintain the 0.2-per-cent accuracy. A further advantage of a buffer stage would be that it could act as a clipper, giving a constant output magnitude over the operating range instead of one which varied with the frequency. This output can be transmitted over any desired link to an indicating station giving a representation of the voltage measured V_{in}.

It was stated that the saturation flux of Hipernik V changes about 0.07 per cent per degree centigrade and that this would vary the constant of proportionality in $f=KV_{in}$. If the core were enclosed in a constant temperature box held to a variation of ±2.5 degrees centigrade, the proportionality would change by only ±0.2 per cent. This temperature limit should not be difficult to obtain in a small, inexpensive oven.

If a unidirectional input voltage wave form, shown in Fig. 5, is applied to the input terminals, the unit will reverse the output polarity each time the volt-second area under the input curve from the time of the previous reversal reaches the value necessary to move the core flux from one saturation point to the other. The output voltage follows the same wave shape as the input, except that each output pulse has the same volt-second area and every other pulse is the mirror image of the input.

Rewriting $V_{in}=N(d\phi/dt)$ and integrating over a complete half-cycle of flux change

$$V_{in}dt=N\int_{\phi_m}^{\phi_m}d\phi=2N\phi_m$$

Thus, twice the number of turns times ϕ_m determines the volt-second area of the input which is required for each output pulse. This is then an analogue-to-digital converter in that the digital output (number of pulses) is the representation of the analogue input (integral of the applied unidirectional voltage). A count of the number of output pulses during a fixed time period would give the integral of the applied voltage over that time.

Conclusions

In this paper a simple and reliable circuit has been illustrated to convert direct to alternating current. Several of its applications—precision telemetering and integrating—have been described. Little or no effect on the operation is noted when transistors are replaced or are interchanged. It was emphasized that junction transistors used as switches make useful circuit components which will operate over widely varying ambient conditions.

Discussion

George C. Uchrin (Signal Corps Engineering Laboratories, Fort Monmouth, N. J.): A circuit similar to the one described in the paper was devised in January 1954 by W. O. Taylor and the writer.[1] The basic circuit and mode of operation are the same. It was found that grounded base as well as grounded emitter could be used. It was also found that almost any type of core material could be used and still obtain good wave form.

The interest of the Laboratories in this circuit is its use in low-voltage to high-voltage d-c transformation for the operation of various types of communications equipment. Power converters have been built which were capable of delivering approximately 60 watts output from a 24-volt d-c source.

1. A New Self-Excited Square-Wave Transistor Power Oscillator, **George C. Uchrin, Wilfred O. Taylor.** *Proceedings*, Institute of Radio Engineers, New York, N. Y., vol. 43, Jan. 1955 p. 99.

A. G. Milnes (Carnegie Institute of Technology, Pittsburgh, Pa.): The switching transistor oscillator described by Dr. Royer is of considerable interest as a supply source for the operation of magnetic-amplifier equipment. The efficiency is high, the source impedance is suitably low, and the reliability is likely to be good when high-power conservatively rated transistors are available. Such converters may therefore tend to replace rotating electric machines supplying small amounts of 400-cycle-per-second power in various military applications.

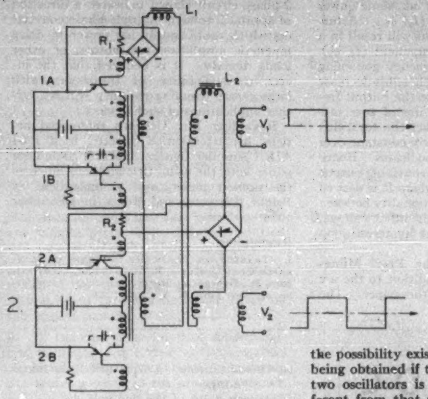

Fig. 6. Arrangement of switching-transistor oscillators

If magnetic-amplifier equipments are supplied from independent transistor oscillators it is probable that design frequencies will increase since performance for a given weight is thereby improved. This is true up to at least 2,400 cycles per second, which happens to be a frequency for which appreciable experience has been gained in magnetic-amplifier design and in the operation of associated apparatus such as motors, gyros, and torque relays.

Two switching-transistor oscillators of the same frequency can be interlinked so as to provide outputs which differ in phase by 90 degrees in a prescribed sequence. One possible arrangement is shown in Fig. 6. The transistor oscillators *1* and *2* are of the general type considered by Dr. Royer and may be operated from the same d-c source although for clarity in the diagram two separate batteries are shown. The capacitors across transistors *1B* and *2B* are not concerned with phase locking but may be desirable in the basic circuits to suppress abnormal high-frequency oscillations when the circuits are first energized. The phase-locking circuits are those containing the saturable reactors L_1 and L_2 and the rectifier bridges which apply voltages to the resistors R_1 and R_2. It will be seen that the L_1, R_1 circuit is energized by the sum of the oscillator voltages and the L_2, R_2 circuit by the difference of the voltages.

If the output voltages have a phase difference of exactly 90 degrees, the sum and difference wave forms have pulses of the same mean voltage-time area. The reactors L_1 and L_2 are designed so that the full nonsaturating flux changes occur in them for this condition and so no appreciable voltages appear across R_1 and R_2. If the phase difference between V_1 and V_2 is, however, e.g., less than 90 degrees (V_2 lagging on V_1), the pulse width of V_1+V_2 exceeds the saturation pulse width of L_1 and a residual pulse appears across R_1. This voltage switches off transistor *1A* and so causes reversal of oscillator *1* earlier than normal and therefore increases the phase difference towards the required 90-degree value. If the phase lag exceeds 90 degrees the correction is provided by the phase-locking circuit L_2, R_2 acting on oscillator *2*. Theoretically the possibility exists of no correcting action being obtained if the phase displacement of two oscillators is exactly 180 degrees different from that required, but in practice the oscillators have sufficient slip to ensure that this condition is unstable and presents no difficulty.

A rather similar circuit has been devised in which corrective action is applied to both transistors of the two oscillators and is now under examination. This uses no more components than the circuit illustrated although more windings are required.

The necessary saturation flux swings or voltage-time ratings of reactors L_1 and L_2 are solely related to the rating of the main cores and so the phase-locking action is not disturbed by change in the input voltage to the system. If the voltage-time rating of reactor L_1 is made half of that of L_2 (with the total absorption of L_1 and L_2 adjusted to match the main core), the phase lag obtained is 120 degrees. In this way with three oscillators it is possible to produce a 3-phase supply system. The prospect of obtaining 2-phase and 3-phase systems from the oscillators increases their attractiveness as supply sources.

G. H. Royer: Many different types of applications may be made of the basic d-c to a-c converter described in this paper. Mr. Uchrin's application was in the field of d-c power supply circuitry where a low-voltage direct current is converted to a square-wave alternating current transformed to a high-voltage level and rectified, yielding a good high-voltage d-c source requiring very little filtering because the rectified square wave has practically no ripple.

In such an application the only requirements are that the output voltage wave form be square to reduce the filtering required, and that the regulation of the transformer be good in order to maintain good voltage regulation. However, Prof. Milnes' discussion relates to the use of the device to supply a-c power to a magnetic amplifier or other a-c load, thus eliminating the necessity of operating at a frequency fixed by the available line power. In such an application it is desirable to maintain the output frequency constant under varying loading conditions.

The use of ordinary transformer steel as suggested by Mr. Uchrin has the obvious advantage that it is less expensive than square-loop material; however, it would not be satisfactory in Prof. Milnes' application because when such steel is used the frequency shifts considerably with a change in load. To illustrate the reason for this behavior, consider the operation of a circuit similar to that shown in Fig. 2 combining transistors and ordinary transformer steel. For a fixed input voltage V_{in} the base drive voltage to transistor *A* will be $V_{in}(N_1/N_2)$. The characteristic of transistor *A* is such that it will have a very low voltage drop as the current increases up the value I_x determined by the transistor current gain. Beyond this current the transistor voltage drop increases sharply for little further increase in current. A typical normal $\phi-i$

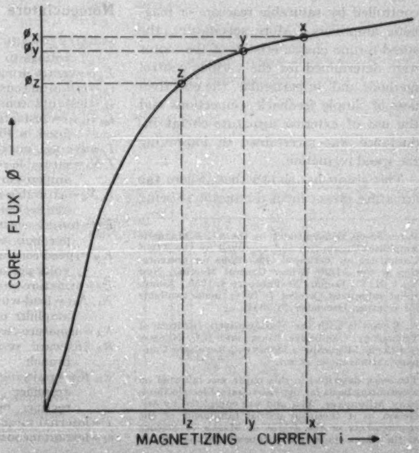

Fig. 7. Normal ϕ-i curve for transformer steel

curve for transformer steel is shown in Fig. 7. As the input voltage is applied to winding 2, the flux increases linearly until it reaches ϕ_x corresponding to the point at which the magnetizing current is equal to I_x. Here the voltage drop across the transistors increases rapidly, the voltage across the transformer falls, the induced base voltage falls, and the current in the transistor is reduced from I_x toward zero in the same manner as described in the paper. The sharp wave form is determined by the sharp current limitation and voltage increase of the transistor at the current I_x. Any output load current will be reflected back into winding 2 and will be a part of this total transistor current I_x. Thus only the difference between the reflected load current and the transistor maximum current I_x will be available to magnetize the core, and switching will occur at some lower value of current and flux (I_y, ϕ_y). A further increase in load current will result in a still lower magnetizing component (I_z, ϕ_z). It is evident from the frequency governing expression $f=V_{\text{in}}/(4N\phi_m)$ that this decrease in the flux swing will cause the output frequency to increase. The use of core materials with a flat top makes the total flux swing $2\phi_m$ much more nearly constant over a wide range of loading conditions. Hence in applications where a constant output frequency is required, or where it is desired to maintain a direct proportionality between the output frequency and the input voltage, it is necessary to use square hysteresis loop core material.

The circuitry offered by Prof. Milnes should provide a useful addition to the a-c power supply discussed in this paper. The 2-phase circuit shown indicates a direction of approach toward multiple-phase converters which could supply a-c power to drive magnetic amplifiers, a-c motors, or other loads directly. It is believed that the increased availability of transistors with large power handling capacity will see further applications of such devices.

Regarding Mr. Uchrin's referenced article, his attention is directed to a 1954 AIEE Summer General Meeting conference paper with the same title and substance as the present paper, and to an article by Bright, Pittman, and Royer in December 1954.[1]

Magnetic-Amplifier Control of D-C Motors

A. KUSKO
MEMBER AIEE

J. G. NELSON
NONMEMBER AIEE

ALTHOUGH considerable work has been done on the operation of adjustable-speed d-c motors with armature power supplied by thyratrons[1] and by metallic rectifiers controlled with adjustable transformers,[2,3] there is little information available on the use of magnetic amplifiers for this purpose. For this reason, an analytical and experimental study was made of the steady-state operation of a d-c motor with armature power supplied through metallic rectifiers and controlled by saturable reactors or magnetic amplifiers. More specifically, the speed-torque characteristics of the motor were determined for the various control methods and, in particular, the effectiveness of simple feedback connections and the use of external armature-circuit inductance was ascertained in improving the speed regulation.

This study has shown that, where the armature power for a d-c motor is being supplied by metallic rectifiers, adequate speed regulation and control can be obtained by the use of magnetic amplifiers with simple feedback circuits. This is particularly true where the motor speed must be adjusted remotely or by the resultant of two or more control signals. Moreover, the speed-torque characteristics of the motor and the design parameters of the auxiliary apparatus are relatively straightforward to predict.

Nomenclature

$a=E_g/V_m$ = ratio of armature generated voltage to peak line voltage
E_g = average armature generated voltage
i_A = instantaneous armature current
i_L = instantaneous line current
i_a, i_{I}, i_{II} = instantaneous currents as defined in Fig. 14
I_f = average motor field current
I_cN_c = saturable-reactor control-winding ampere-turns per core, average
I_LN_L = saturable-reactor load-winding ampere-turns per core, average
K_T = torque constant of the motor, torque per unit armature current
K_N = speed constant of the motor, generated volts per unit speed
L_A = armature-circuit inductance
N_{I}, N_{II} = load-winding turns on magnetic-amplifier cores I and II
R_A = armature-circuit resistance
R_R = forward resistance of each rectifier branch
R_{I}, R_{II} = resistance sum of one magnetic-amplifier load winding and one rectifier branch
T = internal torque of the motor
v_l = instantaneous line voltage
v_A = instantaneous armature terminal voltage
V_m = peak value of the line voltage
X_1, X_2, X_3, X_4 = branches of the bridge rectifier
α = firing angle at which core I saturates
α_1 = angle at which core I begins to absorb voltage
α_2 = angle at which rectifier X_3 begins to conduct
α_3 = angle at which the load-winding current i_{I} becomes zero
ϕ = flux reset on the magnetic-amplifier cores
$\theta=\tan^{-1}\dfrac{\omega L_A}{R_A}$ = impedance angle of the armature circuit

Analysis

The system to be considered consists of a d-c motor with constant field current, a full-wave metallic rectifier for supplying the armature power, and a saturable magnetic device for controlling the armature voltage. With respect to this system the purpose of this section is to review briefly the effect of armature-circuit inductance on the continuity of the armature current, to show what characteristics can be anticipated from control by saturable magnetic devices, and to indicate how the

Paper 55-60, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 7, 1954; made available for printing December 3, 1954.

A. KUSKO is with the Massachusetts Institute of Technology, Cambridge, Mass., and J. G. NELSON is with the Minneapolis-Honeywell Regulator Company, Minneapolis, Minn.

The work described in this paper was initiated on a consulting basis for the Hevi Duty Electric Company, Milwaukee, Wis., and was completed by Mr. Nelson as a thesis in partial fulfillment of the requirements of the degree of Master of Science at the Massachusetts Institute of Technology.

characteristics and the design parameters can be calculated. In the analysis of these systems the following simplifying assumptions are made:

1. The armature speed and generated voltage remain constant over each cycle of armature current pulsation.

2. The metallic rectifiers can be represented electrically by a constant forward resistance and an infinite reverse resistance.

3. The hysteresis loop of the core materials used in the magnetic-amplifier and saturable-reactor cores has zero coercive force and infinite permeability below saturation and zero permeability above saturation.

4. Any voltages induced in the control windings of the magnetic amplifier or saturable reactor have negligible effect on the control current.

5. In the case of magnetic-amplifier control, inductance is added to the armature circuit of sufficient magnitude to maintain continuous current in the armature circuit.

6. In the case of magnetic-amplifier control, the armature current is zero at the instant either one of the magnetic-amplifier cores saturates. This assumes that the inductance connected in series with the armature, as discussed under item 5, is just sufficient to maintain continuous conduction.

7. In the case of magnetic-amplifier control, the armature current consists of only two well-defined periods per half-cycle of line voltage and that the circuit switches from one period to the other at $\omega t=\pi$ of the line voltage.

These last two assumptions are directly associated with the analysis of the magnetic-amplifier circuit given in the Appendix and are restated and discussed in more detail in that section.

Operation of a D-C Motor with Armature Voltage Supplied by a Rectifier

The operation of a d-c motor with armature power supplied by a full-wave rectifier, shown in Fig. 1, is basic to this discussion and will be reviewed briefly. In this system, as is well known, the armature current is pulsating. For zero armature inductance, the armature current i_A exists in pulses only at those times when the magnitude of the line voltage v_l exceeds the armature generated voltage E_g. However, when armature inductance is present, the armature current exists outside this interval; typical wave forms of armature voltage v_A and armature current i_A are shown in Fig. 2 for two extremely different values of armature inductance. The wave forms of Fig. 2(A) are typical with only the inductance of the armature itself being considered. Fig. 2(B) illustrates the effect of considerably increasing the armature-circuit inductance by adding an inductor in series with the motor armature. From these diagrams it is apparent that there are two possible modes of operation for a d-c motor supplied from a full-wave rectifier circuit depending on the relative inductance of the armature circuit. For the operation illustrated in Fig. 2(A), the armature current appears in discrete pulses, there being two such pulses during each cycle of the supply frequency. This condition is known as discontinuous conduction. The second type of operation, known as continuous conduction, is illustrated by the wave forms in Fig. 2(B). The armature-circuit inductance in this case is of sufficient magnitude to maintain current in the armature circuit at all times.

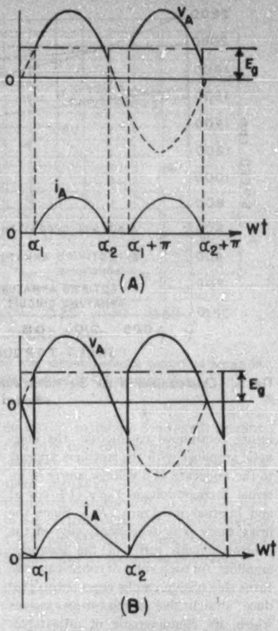

Fig. 2. Wave forms of armature current and armature terminal voltage for (A) discontinuous conduction and (B) continuous conduction

Saturable Reactor Control of Armature Current

The circuit for a saturable reactor as used to control the average current applied to the rectifier-armature circuit is shown in Fig. 3. A saturable reactor is inherently a constant-current device to the extent that, in the region of proportional-current operation, the average control-winding ampere turns I_cN_c and half-cycle average load-winding ampere turns I_LN_L in each core are equal[4]

$$I_LN_L=I_cN_c \tag{1}$$

When the motor is operating in the region of discontinuous conduction, the half-cycle wave forms of the armature and reactor load-winding currents are nearly identical so that the average values over that interval can be considered equal

$$I_A=I_L \tag{2}$$

The internal torque of the motor operating with constant field current is

$$T=K_TI_A=K_T\frac{N_c}{N_L}I_c \tag{3}$$

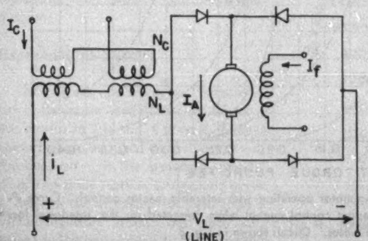

Fig. 3 (left). Circuit for saturable-reactor control of armature current

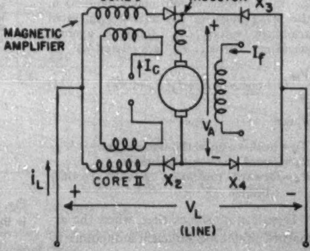

Fig. 4 (right). Circuit for magnetic-amplifier control of armature voltage

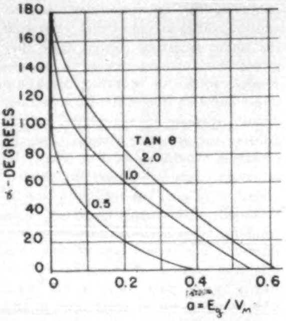

Fig. 5. Plot of equation 6 of α as a function of a for three values of tan θ

It is thus determined by the average control current and is theoretically independent of speed. When the motor is operating in the region of continuous conduction, the average armature current becomes greater than the half-cycle average value of the line current so that equation 3 is no longer valid. For adjustable-torque operation, the region of continuous conduction is of no interest.

Magnetic-Amplifier Control of Armature Voltage

A self-saturating magnetic-amplifier circuit is shown in Fig. 4 for controlling the voltage applied to the armature of a d-c motor; the circuit consists of two separate magnetic-amplifier cores I and II and four metallic rectifiers X_1, X_2, X_3, and X_4 connected in a bridge circuit. A complete analysis of this circuit is given in the Appendix.

Two important relationships stem directly from this analysis. They are as follows:

1. If the armature current is continuous, the firing angle α of the magnetic amplifier is practically independent of the speed of the motor and depends solely on the control-winding ampere turns.
2. In the region of continuous conduction, the firing angle α, the average generated armature voltage E_g, and the average armature current I_a, are related by

$$\frac{V_M}{\pi}(1+\cos\alpha)=E_g+I_A(R_A+2R_R) \tag{22}$$

where

V_M = peak value of the line voltage
R_A = armature-circuit resistance
R_R = forward resistance of each rectifier branch

Equation 22 shows that, when the armature circuit has sufficient inductance to insure continuous conduction, the magnetic amplifier with the rectifiers appears to the armature as a voltage source of internal average voltage $V_M/\pi\ (1+\cos\alpha)$ and internal resistance $2R_R$. Since the firing angle α is dependent only on the control ampere turns of the magnetic amplifier, for each value of control ampere turns this system can be expected to produce straight-line speed-torque curves which are characteristic of adjustable-voltage systems and can be predicted as easily as those for the motor alone.

The magnitude of armature inductance required to maintain continuous conduction can be determined by using the current equations derived in the Appendix. The armature current consists of two separate periods during each half-cycle of the supply frequency. These currents are given in the Appendix as

$$i_A=i_1=\frac{V_M}{(R_A+2R_R)}\left(\cos\theta\sin(\omega t-\theta)-a+[a-\cos\theta\sin(\alpha-\theta)]\epsilon^{-\frac{\omega t-\alpha}{\tan\theta}}\right)_{\omega t=\alpha}^{\omega t=\pi} \tag{24}$$

$$i_A=i_a=\left(I_0+\frac{E_g}{(R_A+2R_R)}\right)\epsilon^{-\frac{\omega t-\pi}{\tan\theta}}-\left.\frac{E_g}{(R_A+2R_R)}\right|_{\omega t=\pi}^{\omega t=\pi+} \tag{25}$$

where I_0 is the value of the armature current in equation 24 at $\omega t=\pi$. For continuous conduction it is necessary that $i_A=0$ at the instant $\omega t=\pi+\alpha$. Setting $i_A=0$ for $\omega t=\pi+\alpha$ and rearranging to a dimensionless form, equation 25 becomes

$$\frac{(R_A+2R_R)I_0}{V_M}=a\left(\epsilon^{\frac{\alpha}{\tan\theta}}-1\right) \tag{4}$$

The expression $(R_A+2R_R)I_0/V_M$ is determined by letting $\omega t=\pi$ in equation 24

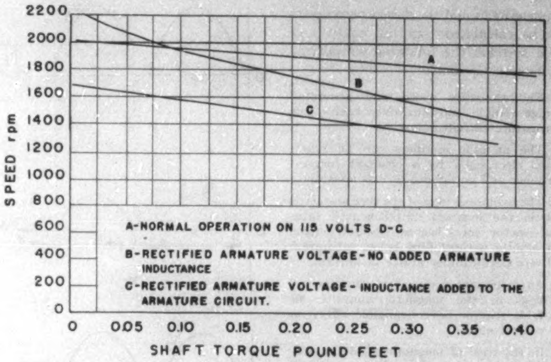

Fig. 6. Characteristics of the d-c motor without external control and with armature power supplied as shown

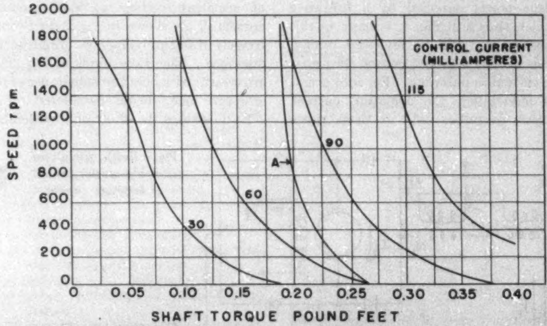

Fig. 7. Characteristics of the d-c motor operating with saturable-reactor control. Curve A is the characteristic for 60-milliampere control current when corrected for the rotational loss of the motor. Circuit shown in Fig. 3

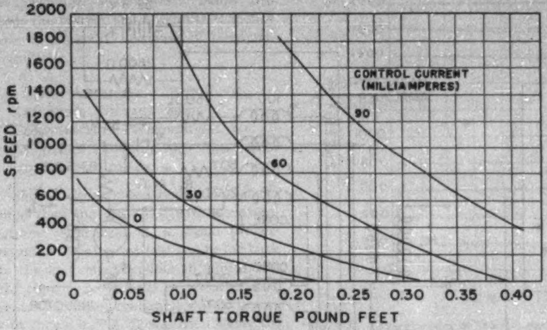

Fig. 8. Characteristics of the d-c motor operating with saturable-reactor control as shown in Fig. 3 but with an inductance of 0.20 henry added to the armature circuit

and rearranging to a dimensionless form

$$\frac{I_0(R_A+2R_R)}{V_M}=\cos\theta\sin(\pi-\theta)-a+\left[a-\cos\theta\sin(\alpha-\theta)\right]\epsilon^{-\frac{\pi-\alpha}{\tan\theta}} \qquad (5)$$

Equating equations 4 and 5 yields

$$a\left(\epsilon^{\frac{\alpha}{\tan\theta}}-1\right)=\cos\theta\sin(\pi-\theta)-a+\left[a-\cos\theta\sin(\alpha-\theta)\right]\epsilon^{-\frac{\pi-\alpha}{\tan\theta}} \qquad (6)$$

Equation 6 expresses the condition which must be met for continuous conduction in terms of a, α, and θ. A family of curves can be constructed from equation 6 to be used for determining the magnitude of armature-circuit inductance required to maintain continuous conduction. Because of the limits set on equation 4 and 5, this inductance will be that just required to maintain conduction throughout the cycle for a particular value of α, θ, and a. A graph of this form is shown in Fig. 5 where equation 6 is plotted for three different values of armature-circuit impedance angle θ($\tan\theta=0.5$, 1.0, and 2.0). The region to the right of any particular curve represents the region of discontinuous conduction while the one to the left represents the region of continuous conduction.

Experimental Results

The normal speed-torque characteristics of the motor used in this investigation are shown in Fig. 6. Curve *A* denotes the armature supplied from the 115-volt d-c line, curve *B* the armature supplied from a metallic-rectifier bridge, and curve *C* denotes the armature supplied from a metallic-rectifier bridge but with sufficient inductance added to the armature circuit to maintain continuous conduction; the field current in all three cases is constant. Note the improvement in the speed regulation shown in curve *C* as compared with curve *B*. The motor used in all of this work is a 1/8-horsepower 1,725-rpm 115-volt 1.5-ampere d-c shunt motor. The motor has no interpoles.

Saturable-Reactor Control of Armature Current

The speed-torque characteristics of the motor for the saturable-reactor control circuit shown in Fig. 3 are given in Fig. 7 with reactor control current as the parameter. The saturable reactor is a 3-legged unit, rated 220 volts, 3.0 amperes. The values of shaft torque on the abscissa are the measured brake-torque values. The internal torque is calculated as the sum of the shaft torque and the combined rotational loss torques of the motor, brake, and tachometer. This correction is made for the 60-milliampere control-current curve and is shown as curve *A* in Fig. 7.

The curves shown in Fig. 7 illustrate the adjustable-torque characteristic obtained with saturable-reactor control. At low speeds, constant torque is no longer maintained for fixed values of control current because of the onset of continuous conduction. Under conditions of continuous conduction, the average armature current exceeds the average line current; this results in an increase in torque with a decrease in speed. As an illustration of the effect of continuous conduction on the constant-torque characteristics, the curve shown in Fig. 8 was measured using the circuit shown in Fig. 3 with an inductance of 0.20 henry connected in series with the armature. This inductance was sufficient to maintain continuous conduction over the entire lower range of motor speeds producing the pronounced departure of these curves from the ideal constant-torque characteristic. For this reason, armature-circuit inductance must be kept to a minimum if the torque is to be a function only of the control current and not of the speed in the circuit shown in Fig. 3.

Magnetic-Amplifier Control of Armature Voltage

Experimentally determined speed-torque characteristics for the magnetic-amplifier bridge circuit shown in Fig. 4 are given in Fig. 9; shaft torque is the measured brake torque. The magnetic amplifier used in this work is a commercially available 60-cycle-per-second unit, rated 1.1 amperes, 180 watts.

The relationship between average applied voltage, motor internal torque, and speed is derived in the Appendix and is

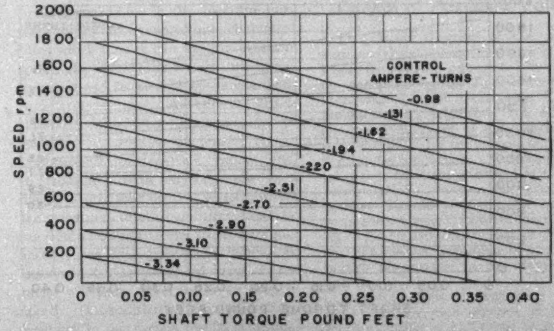

Fig. 9. Characteristics of the d-c motor operating with magnetic-amplifier control, as shown in the circuit of Fig. 4

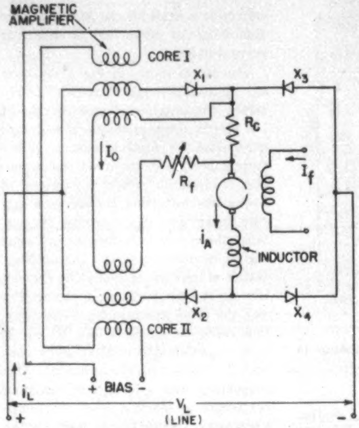

Fig. 10. Circuit for magnetic-amplifier control of the d-c motor with compensation proportional to armature current

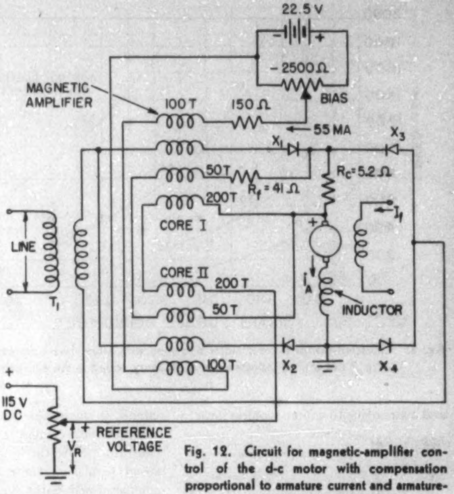

Fig. 12. Circuit for magnetic-amplifier control of the d-c motor with compensation proportional to armature current and armature-voltage feedback

$$n=\frac{1}{K_n}\left(\frac{V_M}{\pi}(1+\cos\alpha)-\frac{T}{K_T}(R_A+2R_R)\right) \tag{23}$$

To verify the validity of equation 23, the experimental curves must be corrected for rotational loss to obtain internal torque. Consider, e.g., the curve for 0.98 control ampere-turns. When this curve is corrected for rotational loss, the drop in speed at full load is 0.450 of the no-load speed. The per-unit resistance of the armature circuit including the resistance of the external inductor is 0.20 and the per-unit voltage drop of one rectifier branch is approximately 0.130, based on the source voltage at no-load speed and the full-load armature current. The calculated per-unit speed regulation is then 0.20+2×0.13=0.46, which agrees closely with the given experimental value.

The speed regulation obtained with this basic magnetic-amplifier circuit can be improved by decreasing the rectifier forward resistance to as low a value as possible, or by employing some type of feedback or compensation to increase the average voltage applied to the armature in proportion to the average armature current or torque as the load is increased. With the metallic rectifiers now available commercially, the forward resistance cannot be made appreciably less than that encountered in this investigation, so that feedback or compensation methods are required to obtain an improvement in speed regulation.

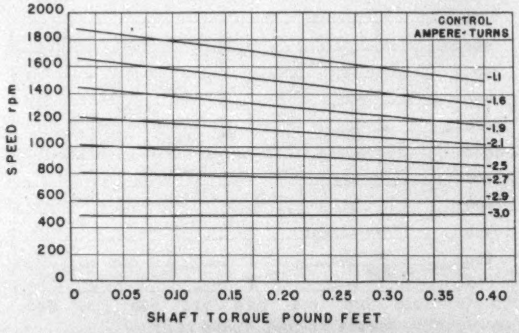

Fig. 11. Characteristics of the d-c motor operating with the magnetic-amplifier control circuit shown in Fig. 10. Compensation proportional to armature current

Magnetic-Amplifier Control of Armature Voltage with Compensation Proportional to Armature Current

Since the speed-torque characteristics shown in Fig. 9 are straight lines, the simplest method of improving the speed regulation of the circuit shown in Fig. 4 is by the use of compensation proportional to armature current, as shown in Fig. 10. In this scheme, a voltage proportional to armature current is applied to a second control winding on the magnetic-amplifier cores. The relative polarity of the resulting current I_0 is such that the magnetic-amplifier firing angle is decreased with increasing load on the motor. The speed level (no-load speed) is adjusted with the bias-control current, while the speed drop (compensation) is controlled by the compensation-circuit resistance R_f.

The speed-torque characteristics shown in Fig. 11 are an example of the type of speed regulation that can be obtained with this circuit. To obtain the data shown in Fig. 11, the compensation-circuit resistance was adjusted for flat regulation at 600 rpm. For speeds above 600 rpm, the speed regulation becomes progressively greater (more drop) although the regulation for a no-load speed of 1,900 rpm is only 0.23 per unit, which is a considerable improvement over that obtained with no

Vol. 7
Pt. 1
1955

compensation whatsoever. Below 600 rpm, the system has a definite tendency toward instability because of overcompensation.

Magnetic-Amplifier Control of Armature Voltage with Compensation Proportional to Armature Current and Armature-Voltage Feedback

Should closer speed regulation be desired than that obtained with armature-current compensation, a signal proportional to armature voltage can be fed back to the magnetic amplifier in addition to the signal proportional to armature current. In the experimental work, the circuit shown in Fig. 12 was used where the three control windings on the magnetic-amplifier core serve as a bias winding, compensation winding, and feedback winding. The feedback-winding signal is proportional to the difference between the armature terminal voltage and a reference voltage, so that this is a true feedback control system. The motor speed is adjusted by means of the reference voltage V_R. An isolating transformer T_1 was used in the experimental work so that one side of the armature circuit could be grounded to the particular d-c source used for reference.

A set of experimentally determined speed-torque curves for this control scheme is illustrated in Fig. 13 where speed and torque are shown for parametric values of reference voltage. The circuit parameters and number of control-winding turns used in obtaining these characteristics are given in the diagram shown in Fig. 12. These curves illustrate the characteristics that can be obtained with magnetic-amplifier control of armature voltage when adequate compensation and feedback are used. The system is stable at all speed levels and is critically damped or slightly overdamped in response to a change in either reference voltage (speed) or load. No definite data were taken regarding response time.

The experimental characteristics shown in Fig. 13 were measured with continuous conduction in the armature circuit. For this condition no stabilization or filtering was necessary in any of the control windings to maintain a stable system. With the external inductor removed so that conduction was discontinuous, the system became unstable. Inductors of approximately 10 henrys were added to each of the control windings to alleviate this condition and, although this reduced the oscillations in speed to a certain extent, the system still had definite tendencies to oscillate at any set speed level. From this experience it is apparent that continuous conduction is essential for stable operation of this circuit unless further stabilization techniques are to be employed.

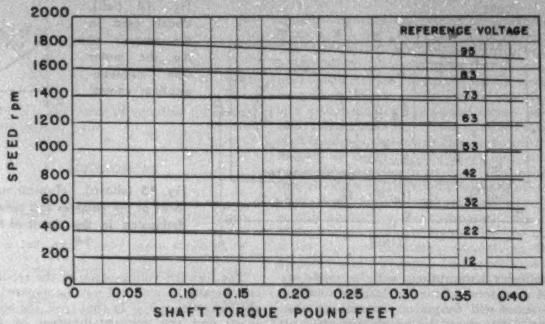

Fig. 13. Characteristics of the d-c motor operating with the magnetic-amplifier control circuit shown in Fig. 12. Compensation proportional to armature current and armature-voltage feedback

Conclusions

The control of the armature voltage of an adjustable-speed d-c motor by means of saturable magnetic devices produces well-defined torque-speed characteristics. Saturable-reactor control results in nearly constant-torque characteristics at each level of control current; magnetic-amplifier control produces approximately constant-speed characteristics at each level of control current.

Continuity of conduction of the armature current influences the shape of the torque-speed characteristics of the controlled motor. With saturable-reactor control, discontinuous conduction in the armature current results in speed-torque characteristics adhering closely to constant torque levels. On the other hand, under magnetic-amplifier control, continuous conduction in the armature current results in speed-torque characteristics which may not be exactly constant speed, but at least are straightline in nature and can be altered by simple feedback arrangements. An external armature-circuit inductor is necessary to achieve continuous conduction.

Compensation feedback proportional to armature current may be applied to a magnetic-amplifier control system, where the armature current has continuous conduction, to obtain at one speed a torque-speed curve with zero speed regulation; the remaining torque-speed curves in the range will show either a rise or drop in speed. The addition of armature-voltage feedback to this system results in torque-speed curves with close-speed regulation at all speed levels in the range.

The type of magnetic-amplifier control system described is suited to applications requiring speed regulation of the order of 2 per cent at one speed and a speed range of the order of 10-or-20 to 1. For this purpose, the system is certainly simpler than a thyratron system and is about as complex as an adjustable-transformer metallic-rectifier system where the field winding of the motor is supplied from a separate rectifier. The magnetic amplifier has the further advantage that it can be controlled remotely, at low power levels, and from multiple signals.

Further work is needed on methods for predicting the dynamic performance of such systems. Experience in the experimental work on the units described indicated that the transient response of the motor speed to changes in control current was fast and adequately damped.

Appendix I. Analysis of the Magnetic-Amplifier Circuit for Control of Armature Voltage

The circuit diagram of the magnetic amplifier and d-c motor is shown in Fig. 14 where the motor is represented by an internal generated voltage E_g in series with an inductance L_A and a resistance R_A. The inductance L_A represents the armature-winding inductance plus an external inductance added for the purpose of obtaining continuous conduction. The resistance R_A represents the total resistance of the armature winding, brushes, and external inductor. The forward rectifier resistance is assumed constant and is represented by R_R. The resistance of one load winding and the forward resistance of one rectifier branch are lumped in the resistances R_I and R_{II}.

In this analysis, the equations will first be written for each separate interval occurring during a half-cycle of operation. When this has been accomplished, necessary

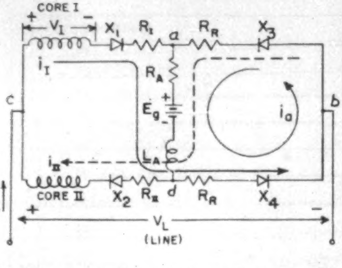

Fig. 14 (left). Circuit used in the analysis of the d-c motor with magnetic-amplifier control

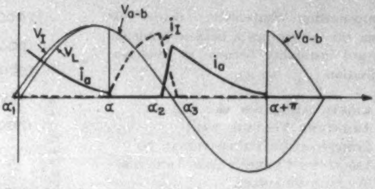

Fig. 15 (above). Typical wave forms of the voltages and currents designated in the circuit of Fig. 14

simplifying assumptions will be made so that an expression can be obtained relating the speed and torque of the motor. The approximate wave forms of currents and voltages are shown in Fig. 15, which also serves to define the various intervals of operation. The assumptions relating to this analysis are given previously in the section entitled "Analysis."

The Angle $\omega t = \alpha_1$

The angle α_1 is defined as the angle at which core I begins to absorb voltage. During the negative half-cycle of the supply voltage $v_l = V_m \sin \omega t$, the flux in core I has been reduced below saturation to a value depending on the control ampere-turns.

The currents i_I, i_{II}, and i_a are defined in Fig. 14; i_I is the current in the magnetic-amplifier load winding placed on the core I, i_{II} is the current in the load winding on core II, and i_a is a current in the loop *a-d-b*. Following the time $t = \alpha_1/\omega$, core I is absorbing voltage, the current $i_I = 0$, so that the voltage applied to core I is

$$v_I = V_M \sin \omega t + i_a R_R \tag{7}$$

where $i_a R_R$ is the voltage drop across the rectifier X_3. The flux in core I will begin to increase toward saturation when $v_I > 0$ or when

$$V_M \sin \omega t \geq -i_a R_A \tag{8}$$

The Interval $\omega t = \alpha_1$ to $\omega t = \alpha$

The angle α is defined as that angle at which magnetic amplifier core I saturates and is referred to as the firing angle. The core saturates when

$$\varphi = \frac{1}{N_I}\int_{\alpha_1}^{\alpha} v_I dt = \frac{1}{N_I}\int_{\alpha_1}^{\alpha} (V_M \sin \omega t + i_a R_R) dt \tag{9}$$

where φ is the flux reset during the preceding half-cycle and N_I are the load-winding turns on core I. During this interval, from Fig. 14

$$i_a R_R = -\left(E_g + L_A \frac{di_a}{dt} + i_a(R_A + R_R)\right) \tag{10}$$

so that the core will saturate when

$$\varphi = \frac{1}{N_I}\left\{\int_{\alpha_1}^{\alpha}\left[V_M \sin \omega t - \left(E_g + L_A \frac{di_a}{dt} + i_a(R_A + R_R)\right)\right]dt\right\} \tag{11}$$

The forward voltage drop of the rectifier can usually be assumed small compared to the line voltage v_l. In that case, the angle $\alpha_1 = 0$ and the voltage absorbed by the core in the interval α_1 to α is the line voltage v_l. The relationship between the reset flux φ and the firing angle α is then independent of voltage E_g and the speed. This only occurs because the armature current is forced to be continuous throughout the interval and rectifier X_3 remains conducting.

The Interval $\omega t = \alpha$ to $\omega t = \alpha_2$

The angle $\omega t = \alpha_2$ is defined as the angle at which the rectifier X_3 begins to conduct, following the pulse of current through load winding I; this provides a circulating path around the armature circuit for the current i_a. At $\omega t = \alpha$, core I saturates and the voltage $V_M \sin \alpha$ is applied instantaneously between points *a* and *b*; see Fig. 14. If, as will usually be the case at that instant

$$V_M \sin \alpha \geq i_a R_R \tag{12}$$

the rectifier X_3 will block and the current will commutate, so that

$$i_I = i_a \Big|_{\omega t = \alpha} \tag{13}$$

Rectifier X_3 will continue to block as long as $v_{ab} > 0$. The current in load winding I and the armature during the interval α to α_2 is then the solution to the equation

$$V_M \sin \omega t = E_g + L_A \frac{di_I}{dt} + i_I(R_I + R_A + R_R) \tag{14}$$

where the boundary condition for i_I at $\omega t = \alpha$ is given by equation 13. At the instant that

$$v_{ab} = V_M \sin \omega t - i_I R_I = E_g + L_A \frac{di_I}{dt} + i_I(R_A + R_R) = 0 \tag{15}$$

rectifier X_3 will begin to conduct allowing a current i_a to circulate around the loop *a-d-b-a*, as shown in Fig. 14.

The Interval $\omega t = \alpha_2$ to $\omega t = \alpha_3$

The angle $\omega t = \alpha_3$ is defined as the angle at which the load-winding current i_I becomes zero. After $\omega t = \alpha_2$, the equations for the currents i_I and i_a are

$$V_M \sin \omega t = E_g + L_A \frac{d}{dt}(i_I + i_a) + i_a R_A + i_I(R_A + R_I + R_R) \tag{16}$$

$$V_M \sin \omega t = i_I R_I - i_a R_R \tag{17}$$

with the boundary conditions at $\omega t = \alpha_2$ being

$$i_a = 0$$

$$i_I = I_K$$

where $i_I = I_K$ is the value of the solution to equation 14 at $\omega t = \alpha_2$.

The Interval $\omega t = \alpha_3$ to $\omega t = \alpha + \pi$

The angle $\alpha + \pi$ is the angle at which core II saturates in the negative half-cycle of line voltage. During this interval, core I is resetting and the load-winding current $i_I = 0$; the current i_a is the solution to the equation

$$0 = E_g + L_A \frac{di_a}{dt} + i_a(R_A + 2R_R) \tag{18}$$

with the boundary condition

$$i_a = \frac{-V_M \sin \omega t}{R_R}\Bigg|_{\omega t = \alpha_3}$$

This current continues until $\omega t = \alpha + \pi$ when core II fires and the foregoing sequence of currents repeats itself.

The equations pertaining to each distinct interval occurring during a cycle of operation have been established in an implicit form. The current in each of the foregoing intervals begins with a boundary value established by the preceding interval. If these boundary values were to be applied rigorously in the equation solutions which follow, the resulting expression for average load current would be too cumbersome to be of practical value. The solutions which follow, therefore, are based on two simplifying assumptions made for the purpose of obtaining a relatively practical expression for the speed and torque of the d-c motor. These assumptions are listed previously as items 6 and 7 in the section entitled "Analysis" and are discussed further at this point. These are:

1. The external inductance in the armature circuit is just sufficient to maintain continuous conduction; the load-winding current i_I and the circulating armature current i_a are both zero at the instant $\omega t = \alpha$.
2. The load winding current i_I decreases instantaneously to zero at the instant $\omega t = \pi$ and, at this instant, the armature circulating current i_a begins with the value of i_I just before $\omega t = \pi$ as the initial boundary condition. If the voltage drops in the magnetic-amplifier load winding and in the rectifiers X_1 and X_3 are assumed small; this actually is the case since then rectifier X_1 blocks at the same instant that rectifier X_3 begins to conduct.

With the foregoing two assumptions the armature current now consists of only two intervals: From $\omega t=\alpha$ to $\omega t=\pi$

$$V_M \sin \omega t=E_g+L_A\frac{di_I}{dt}+i_I(R_I+R_A+R_R) \tag{14}$$

where

$i_I=0$ at $\omega t=\alpha$

This current decreases instantaneously to zero at $\omega t=\pi$. From $\omega t=\pi$ to $\omega t=\alpha+\pi$

$$0=E_g+L_A\frac{di_a}{dt}+i_a(R_A+2R_R) \tag{18}$$

where

$i_a=i_I$ at $\omega t=\pi$

$i_a=0$ at $\omega t=\alpha+\pi$

Assuming that $R_A+R_R+R_I \simeq R_A+2R_R$ and taking the average values of the terms in equations 14 and 18 over one half-cycle

$$\frac{1}{\pi}\int_{\omega t=\alpha}^{\omega t=\pi} V_M \sin \omega t d(\omega t)=\frac{1}{\pi}\int_{\omega t=\alpha}^{\omega t=\pi} [E_g+i_I(R_A+2R_R)]d(\omega t)+\frac{1}{\pi}\int_{\omega t=\alpha}^{\omega t=\pi} L_A\frac{di_I}{dt}d(\omega t) \tag{19}$$

$$0=\frac{1}{\pi}\int_{\omega t=\pi}^{\omega t=\alpha+\pi} [E_g+i_a(R_A+2R_R)]d(\omega t)+\frac{1}{\pi}\int_{\omega t=\pi}^{\omega t=\alpha+\pi} L_A\frac{di_a}{dt}d(\omega t) \tag{20}$$

Recognize that the flux linkage excursion in the armature-circuit inductance is cyclic such that

$$\int_{\omega t=\alpha}^{\omega t=\pi} L_A\frac{di_I}{dt}d(\omega t)=-\int_{\omega t=\pi}^{\omega t=\alpha+\pi} L_A\frac{di_a}{dt}d(\omega t) \tag{21}$$

The addition of equations 19 and 20 results in a simple expression for the average armature current I_A

$$\frac{V_M}{\pi}(1+\cos \alpha)=E_g+I_A(R_A+2R_R) \tag{22}$$

The relationships for speed and torque, $n=E_g/K_n$ and $T=K_TI_A$, can be substituted in equation 22 resulting in

$$n=\frac{1}{K_n}\left(\frac{V_M}{\pi}(1+\cos \alpha)-\frac{T}{K_T}(R_A+2R_R)\right) \tag{23}$$

Equation 23 is the final expression for the speed of the motor in terms of torque and firing angle. The firing angle α is a function of control current only.

The solutions to equations 14 and 18 for the instantaneous currents are given by Vedder and Puchlowski as[1]

$$i_I=\frac{V_M}{(R_A+2R_R)}\left[\cos \theta \sin (\omega t-\theta)-a+[a-\cos \theta \sin (\alpha-\theta)]\epsilon^{-\frac{\omega t-\alpha}{\tan \theta}}\right]_{\omega t=\alpha}^{\omega t=\pi} \tag{24}$$

$$i_a=\left(I_0+\frac{E_g}{R_A+2R_R}\right)\epsilon^{-\frac{\omega t-\pi}{\tan \theta}}-\frac{E_g}{R_A+2R_R}\Bigg|_{\omega t=\pi}^{\omega t=\alpha+\pi} \tag{25}$$

where I_0 is the value of equation 24 at the instant $\omega t=\pi$.

Discussion

L. A. Finzi (Carnegie Institute of Technology, Pittsburgh, Pa.): One wonders why the authors in their analytical treatment have chosen to introduce a rather artificial assumption; they assume that the external choke used in the armature circuit is just sufficient to cause the armature current to decay to zero immediately before a new firing occurs. The reader observing Fig. 5 recognizes that for any given choke there is only one angle of firing at any shaft speed for which this condition is met and he may worry about the broader use of equation 23, thus derived, to describe the general behavior of the motor.

Equation 23 is valid mathematically over the whole range of motor operation in which continuous flow of armature current prevails. This can be shown by the comparatively simple integration of the linear first-order differential equations written under the sole use of assumption 2 of the Appendix; the dubious assumption 1 is totally unnecessary. As a matter of fact, equation 23 can be written also directly from half-cyclic volt-time area considerations, similar to those that have become most usefully popular in the study of magnetic amplifiers. The half-cyclic volt-time area made available by the amplifier upon firing equals the sum of the volt-time areas of resistive drops and of armature voltage E_g (which at no time is blocked by the rectifiers, if the flow of current is continuous); the half-cyclic volt-time area absorbed by the inductances of the armature circuit obviously is zero.

The particular design described in the paper is characterized by the unusual employment of a large choke in series with the armature; hence the range of torques and speeds over which continuous conduction occurs may be broader than in the operation of practical variable-speed drives of this same type commonly marketed by various manufacturers. But in any case, modes of discontinuous conduction are not unlikely over the range. Here equation 23 no longer applies and other expressions are needed to relate α, E_g, and average armature current. The derivation of such expressions becomes less simple, and one may agree that the process of matching of boundary values would be tedious. However, workable equations and complementary graphical means have been made available.[1] This reference deals with irksome questions arising in the general loading of magnetic amplifiers and gives particular attention to the case of d-c armature circuits in all modes of current flow.

The analysis mentioned was performed to acquire knowledge about armature currents in the various modes of conduction and also about the corresponding currents in the amplifier load windings. In the problem at hand the variables of ultimate interest are the load torque, the shaft speed and the quantity chosen to control the magnetic amplifier; the angle of firing is only a convenient intermediate parameter to be eliminated in the final relationship. The need for knowing amplifier power-winding currents is most evident in the case of armature control by saturable reactors. Equation 3 is based on a presumed identity of currents in armature and amplifier load windings, as the authors recognize that no quantitative agreement should be expected with the experimental results of Fig. 7, especially in the critical region of low speeds. With a more subtle mechanism, dictated by the dynamic characteristics of the cores, the wave form of load-winding current affects the amplifier signal requirements for wanted angle of firing also in the case of many self-saturating amplifiers.[2] Whether or not these recognizable effects should be ignored depends largely on the scope of the amplifier system designer and of the problems he faces.

A. Kusko and **J. G. Nelson**: Professor Finzi correctly points out that the equations for operation of this system were derived on the basis of armature inductance just sufficient to maintain continuous conduction, yet the results were applied over the complete speed range. As he states, the results can be obtained without this assumption. Actually, equations 19, 20, and 21 basically represent the volt-time-area approach to the problem.

Additional armature-circuit inductance was not included merely to obtain continuous conduction and a simpler analysis, but was inserted to obtain the straight-line speed-torque curves that resulted from continuous conduction. These curves then made possible the effective compensating means for improving the speed regulation within the economic considerations of the application for which the drive was studied. We acknowledge the generality of Professor Finzi's work on this type of problem and appreciate the usefulness of his references in handling problems of discontinuous conduction in such circuits.

Equations for the Inductance and Short-Circuit Forces of 3-Phase Busses Comprised of 120-Degree Angles

J. W. MAIER
ASSOCIATE MEMBER AIEE

T. J. HIGGINS
MEMBER AIEE

THREE-PHASE busses comprised of 120-degree-angle conductors, as shown in Fig. 1, possess certain very desirable electrical-mechanical characteristics. Thus, they can be closely nested to the end that the reactance per unit length of bus, and thus the voltage drop per unit length of bus, are much smaller than on other shaped busses of similar current-carrying capacity. Again, 120-degree-angle conductors have considerable mechanical rigidity with which to withstand short-circuit forces. Finally, their shape enables an open, compact construction which simplifies ventilation and heat-dissipation problems, minimizes the space required for installation, and provides easy tap-off to individual loads.

These electrical, mechanical, and physical characteristics render angle conductors especially suited for long heavy-current 3-phase distribution busses where it is desirable to reduce the reactance per unit length to a minimum and to minimize the number of insulating supports so as to reduce the number of possible flashover points. In consequence, 3-phase busses comprised of 120-degree-angle conductors have found increasing use[1-6] as a preferred type of construction for distribution busses in high-capacity generating stations and for heavy-current industrial loads.

To predetermine the operating characteristics of these busses requires knowledge of the a-c resistance, the a-c inductance, the copper temperature under load, and the mechanical forces exerted during short circuit. But, though equations are available for calculating the a-c resistance[7] and copper temperature,[8,9] convenient equations, in terms of the bus dimensions, are not available for calculating the inductance and short-circuit forces. It is obvious, however, that knowledge of these equations is most desirable to the bus designer.

Such equations are derived in this paper, it being assumed that the conductors are nonmagnetic, of such length that end effects are negligible, of uniform thickness, right-cornered, and that they carry currents distributed uniformly over their cross sections. Of these five conditions, the first three are satisfied in practice. The fourth, however, though essential to tractable analysis, is not always true in practice. Angles drawn, rolled, bent, extruded, or otherwise formed in one piece have rounded edges; but the error introduced by neglecting the rounded edges is small and, where necessary, the increase in inductance caused by these rounded edges can be approximated by use of semiempirical equations derived by Dwight and Wang.[10] Finally, though skin and proximity effects render the current density over the cross sections of the bus conductors slightly nonuniform, the analysis in the section entitled "Corrections for Rounded Edges and for Skin and Proximity Effects" of reference 11, the discussion following reference 10, and the experimental results published in references 12 and 13 all indicate that, at power frequencies, the a-c inductance is essentially identical with the d-c inductance.

If, then, the stated five postulates are granted, derivation of the desired equations, though lengthy, is not particularly difficult. The conductor cross sections can, per well-established theory discussed in the following, be considered as combinations of line segments; see Fig. 2. By virtue of the fundamental theorem of geometric mean distance theory, the inductance can be expressed in terms of the geometric mean distances between these line segments. These geometric mean distances can be calculated from known equations,[14-16] as shown under the section entitled "General Relationships." Accordingly, determination of the inductance as a function of the parameters defining the spacing and cross sections of the bus reduces, in essence, to specific formulation of these geometric mean distances and substitution of them in the general equation for the inductance, as explained in the section entitled "Derivation of the General Equation for the Inductance." To check the correctness of the resulting equation, it is noted that, if c in Fig. 2 is set equal to zero, the bus reduces to the simple configuration of Fig. 3 whose inductance is a very simple expression, easily written down. Corroboratively, this simple equation for the bus of Fig. 3 is yielded in the limit as $c \to 0$ by the general equation for the bus of Fig. 2; see section entitled "Corrobation of Equation 15."

The mechanical forces acting on busbar supports during short circuits are determined both by the magnitudes of the mutual electromagnetic forces exerted among the bus conductors and by the elastic properties of the supporting structure: its motional resistance, natural frequencies, and physical nature and arrangement. Comprehensive mathematical studies, substantiated by experimental data, of the individual and collective efforts of these factors and general methods for calculating the magnitudes involved have been advanced by various authors.[17-22] In shorter articles based on the work of Schurig,[17] certain charts, nomograms, and short cuts that facilitate the numerical labor incident to actual calculation have been presented.[23-27] In consequence of the work of these men, it may be taken that, if the designer has knowledge of the physical make-up of the bus structure and of the mutual electromagnetic forces exerted among the bus conductors, he can calculate readily the forces on the bus supports. Obviously, knowledge of the physical make-up of the bus structure is immediately available to the designer. Accordingly, if there are also available to him equations for calculating the mutual electromagnetic forces, he has all that is essential to calculate the bus support stresses.

These desired equations for the electromagnetic forces can be obtained by simple differentiation of the equations for the inductance.[28] The equations so obtained, however, require rather lengthy calculation. An alternative, simple means of approximating the desire values is advanced; see the section

---

Paper 55-126, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 19, 1953; made available for printing November 29, 1954.

J. W. Maier is with the Bell Aircraft Corporation, Buffalo, N. Y., and T. J. Higgins is with the University of Wisconsin, Madison, Wis.

This paper is based upon a thesis supervised by Prof. Higgins and submitted by Mr. Maier to the faculty of the University of Wisconsin in partial fulfillment of the requirements for the degree of Master of Science in electrical engineering.

Much of the content of this paper stems in part from a project originally suggested to Prof. Higgins by the Chase Brass and Copper Company, and is made available herein with their permission.

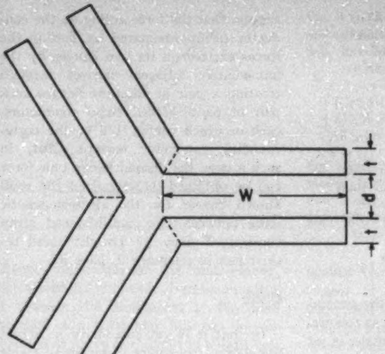

Fig. 1 (left). Cross section of 120-degree-angle bus

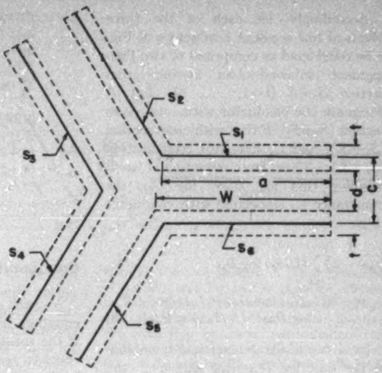

Fig. 2 (right). Cross section of 120-degree-angle line-segment bus

entitled "Equations for Electromagnetic Forces."

Finally, application of the equations for the inductance and electromagnetic forces is illustrated by numerical solution of a typical problem in bus design in the section entitled "An Illustrative Example."

General Relationships

INDUCTANCE

From well-known theory[14,15] it has been derived that the inductance associated with the kth conductor of a bus comprised of r long parallel nonmagnetic conductors, each having a uniform but otherwise arbitrary cross section (reference 15, equation 27), is

$$L_k = -2\sum_{i=a}^{r}(I_i/I_k)\log D_{ik} \text{ abhenries per centimeter of conductor length} \quad (1)$$

where D_{ik} is the geometric mean distance between the kth and ith conductors and I_i is the current (expressed as a complex number) associated with the ith conductor. Equation 1 can be written

$$L_k = \sum_{i=a}^{r} L_{ik} \quad (2)$$

where L_{ik} is the contribution of the ith conductor to the inductance associated with the kth conductor and is given by

$$L_{ik} = -2(I_i/I_k)\log D_{ik} \quad (3)$$

The currents satisfy the Kirchhoff current law

$$I_a+I_b+I_c+\ldots+I_r=0 \quad (4)$$

SHORT-CIRCUIT FORCES

A convenient method[28] for finding the electromagnetic force F_j on the jth conductor of a bus comprised of r conductors is to use the relations

$$F_{jx}=\partial W/\partial x_j \text{ and } F_{jy}=\partial W/\partial y_j \quad (5)$$

where x_j and y_j define the position of the jth conductor in a system of Cartesian co-ordinates x and y in the plane of the cross section of the bus. F_{jx} and F_{jy} are the x and y components respectively of the total force F_j on the jth conductor. W is the energy in the magnetic field of the bus and is given by

$$W=\sum_{k=a}^{r} L_k I_k^2/2 \quad (6)$$

where L_k is given by equation 1. Substituting from equation 6 in equation 5 yields

$$F_{jx}=\sum_{k=a}^{r}(I_k^2/2)\partial L_k/\partial x$$

and

$$F_{jy}=\sum_{k=a}^{r}(I_k^2/2)\partial L_k/\partial y \quad (7)$$

Derivation of the General Equation for the Inductance

The 3-phase bus of Fig. 1 is comprised of three identical conductors, to be distinguished by A, B, and C. In virtue of the geometrical symmetry it follows that the inductances associated with the three conductors are identical, thus $L_A=L_B=L_C=L$. Now attempt to calculate L by appropriate subdivision of each of the three subconductors into two identical subconductors of trapezoidal cross section, as indicated in Fig. 1, and subsequent use of equation 1 would, because of the complicated expressions for the self- and mutual geometric mean distances of these trapezoidal areas, result in an equation more or less intractable for actual numerical computation. An equation tractable to computation can, however, be obtained as follows.

Let the conductors of a bus be comprised of structural shapes such as straps, channels, tubes, angles, or the like and let the ratios of the external major cross-sectional dimensions to the thickness t approximate 10 or greater. Then, per well-established theory[10,12,30] confirmed by experiment, the inductances and electromagnetic forces associated with the actual conductors are closely approximated by those which stem from replacing the cross section of each conductor by line segments having dimensions equal to the mean dimensions of the actual conductor; see Fig. 2. Now the angles used in practice have a total flange width to thickness ratio $2W/t$ of 20 to 50; whence, the bus of Fig. 1 can be well approximated by the line-segment bus of Fig. 2.

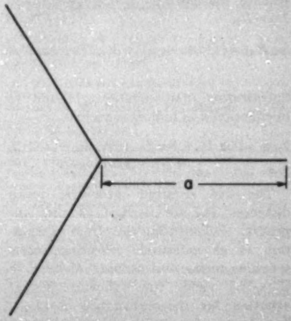

Fig. 3. Cross section of bus with zero spacing

Accordingly, let each of the three identical line-segment conductors of Fig. 2 be considered as comprised of two line-segment subconductors having cross section $S_i=S$ $(i=1, \ldots, 6)$. Let A designate the conductor with total cross section (S_1+S_2), B that with cross section (S_3+S_4), and C that with cross section (S_5+S_6). Then from equation 1, and recalling that $\log D_{ij}= \log D_{ji}$, the inductance L_A associated with conductor A is

$$L_A=-2\sum_{i=A}^{C} (I_i/I_A) \log D_{Ai}$$
$$=-2[(I_A/I_A) \log D_{AA}+(I_B/I_A)\times \log D_{AB}+(I_C/I_A) \log D_{AC}] \quad (8)$$

In virtue of the geometrical symmetry of the bus, $\log D_{AC}=\log D_{AB}$ and the 3-phase currents I_i are balanced, thus displaced 120 electrical degrees apart, say, $I_B=I_A(-0.5+j0.866)$ and $I_C=I_A(-0.5-j0.866)$. Substituting accordngly in equation 8 yields

$$L_A=-2(\log D_{AA}- \log D_{AB}) \quad (9)$$

Now by equation 27 of reference 15, the self-geometric mean distance D_{AA} of conductor A is given by

$$(S_1+S_2)^2 \log D_{AA}=\sum_{i=1}^{2} \sum_{j=1}^{2} S_iS_j \log D_{ij} \quad (10)$$

whence inasmuch as $S_1=S_2$

$$\log D_{AA}=(1/2)[\log D_{11}+\log D_{12}] \quad (11)$$

Again, from equation 27 of reference 15, the mutual geometric mean distance D_{AB} between conductors A and B is given by

$$(S_1+S_2)(S_3+S_4) \log D_{AB} =\sum_{i=1}^{2} \sum_{j=3}^{4} S_iS_j \, 1n \, D_{ij} \quad (12)$$

whence, inasmuch as $S_1=S_2=S_3=S_4$ and $D_{13}=D_{24}$

$$\log D_{AB}=(1/4)[2 \log D_{13}- \log D_{14}+ \log D_{23}] \quad (13)$$

Substituting from equations 11 and 13 in equation 9 as indicated yields

$$L_A=-[\log D_{11}+ \log D_{12}- \log D_{13}-(1/2)\times \log D_{14}-(1/2) \log D_{23}] \quad (14)$$

The five required geometric mean distances D_{ij} are derived in the Appendix. Substituting therefrom in equation 14 as indicated, collecting corresponding terms, and defining K by $K=(C/\sqrt{3}a)$ yields the following general equation for the inductance $L=L_A=L_B=L_C$ associated with each of the three conductors of the bus

$$L=(1/8)[12K^2\ln K+(1-6K-3K^2)\times \ln(1+3K^2)-(2+4.5K+1.5K^2)+ \ln(1+3K+3K^2)+3(2+2K-K^2)\ln(1+K+K^2)+6(1+2K+K^2)\ln(1+K)]+\sqrt{3}/4\{(1-2K) \tan^{-1} [\sqrt{3}(1-K)/(1+3K)]+3(2K+K^2) \tan^{-1} [\sqrt{3}(1-K)/(3+K)]+(1+4K+3K^2) \tan^{-1} [\sqrt{3}K/(2+3K)]+(1+2K) \tan^{-1} [1/\sqrt{3}\times (1+2K)]+(4K-3K^2) \tan^{-1}\times (1/\sqrt{3}K)\}+(3/8)(3K+K^2)\ln\times a+(3/4)(0.5+2K+K^2)\ln 3-\pi/4\sqrt{3} \quad (15)$$

Corroboration of Equation 14

A check on the validity of the general equation 15 is to be obtained as follows. If the spacing c between the angles is set equal to zero, the resulting configuration is that of Fig. 3. In such case, $D_{12}=D_{13}=D_{14}$ and $D_{23}=D_{11}$. Substituting accordingly in equation 14 yields

$$\log D_{AA}=-(1/2)[\log D_{11}-\log D_{12}] \quad (16)$$

Substituting for the geometric mean distances from the Appendix as indicated yields

$$L=(\pi/8\sqrt{3})+(3/8)\ln 3 \quad (17)$$

Corroboratively, substituting $c=0$ in equation 15 yields equation 17.

Determination of Electromagnetic Forces

By assuming an origin of rectangular co-ordinates at the centroid of cross section of the bus with x axis directed, say, parallel to the line segments S_1 and S_6 of Fig. 2, general expressions for the electromagnetic force on any conductor by means of equation 6 could be calculated. However, such equations would prove so lengthy and complicated in form as to render them more or less impractical for numerical computation. A rather simple and sufficiently satisfactory procedure for calculating the electromagnetic force on a conductor is afforded by the following considerations.

In virtue of the geometrical symmetry and of the close spacing between adjacent flanges, the force exerted on a conductor will be primarily caused by the vector sum of the forces exerted on its two flanges by the electromagnetic forces produced on these flanges by the currents in the immediately adjacent flanges of the other conductors. Obviously, the effective mutual electromagnetic force between adjacent flanges will be normal to the flanges; and these flanges of themselves have the shapes of strap conductors. These observations thus suggest that the force acting on the conductor be approximated by finding the forces exerted on its two flanges by the immediately adjacent flanges through treating a pair of adjacent flanges as a pair of parallel-faced strap conductors, each of which carries 1/2 of the corresponding conductor current. But, in such a case, the desired flange pair force can be obtained directly from the well-known curves for the electromagnetic force between two parallel-faced strap conductors given by Dwight[30] and reproduced in reference 2, page 37.

Units

In that it is yet customary in actual bus design to express distances in terms of feet, force in terms of pounds, and so forth, and in that the forms of and subsequent calculations with the general equations are somewhat simplified if centimeter-gram-second rather than meter-kilogram-second units are used, experience is to the effect that it is convenient to advance all equations in terms of centimeter-gram-second units and, subsequently, convert to the various units used in actual design by multiplication with appropriate conversion factors.

Accordingly, with regard to the physical quantities yielded by the equations mentioned to this point, all units, aside from certain permissible and desirable exceptions described in subsequent paragraphs, are in the absolute system: linear dimensions in centimeters, current in abamperes, inductance in abhenrys per centimeter of bus length, energy in ergs per centimeter of bus length, and force in dynes per centimeter of bus length. Multiplying abhenrys per centimeter by 3.048×10^{-5} yields millihenrys per foot of bus length; multiplying by 11.48×10^{-6} yields 60-cycle reactance in ohms per foot of bus length.

In equations for the total inductance associated with the kth conductor, the dimensions of the cross section of the bus can be expressed in any like unit of length. This is to be seen as follows: In equation 1, changing the unit in which D_{ik} is expressed is equivalent to multiplying D_{ik} by a constant, say, s. In turn, the right-hand member of the resulting equation can be written as the sum of the right-hand member of equation 1 plus the term

$$-2\sum_{i=1}^{r} (I_i/I_k) \log s$$

But this term equals zero because of the relationship expressed by equation 4.

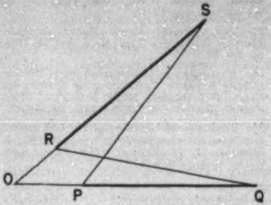

Fig. 4 (left). General disposition of two line segments

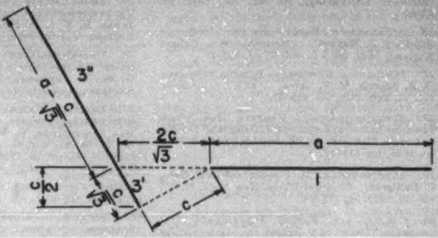

Fig. 5 (right). Cross section for calculation of typical geometric mean distance

Hence, regardless of the unit chosen, the actual inductance is given by equation 1 wherein the dimensions of the cross section of a particular bus can be expressed in terms of the unit of length best suited to ease of calculation for the bus under consideration.

Again, in computing forces, it may prove inconvenient to express the bus dimensions in centimeters since design values are commonly expressed in inches or feet. However, it is easily and similarly established that the dimensions can be expressed in terms of any convenient unit of length, to the end that the computed forces are expressed in terms of dynes per same unit of bus length. Subsequent multiplication by 2.248×10^{-6} yields force in pounds per chosen unit of length.

Thus, to summarize, the desired inductances and forces can be calculated from the derived general equations; therein linear dimensions can be expressed in units of inches or feet (if so desired); and the resulting computed values can be converted directly to the mentioned convenient working units by use of the stated conversion factors.

An Illustrative Example

To illustrate use of equation 15, consider a bus of the form of Fig. 2 having the following typical dimensions: Thickness $t = 3/16$ inch; spacing $d = 1/4$ inch; and width W along the inside of the angle $= 4$ inches. The following values result: $c = (1/4) + (3/16) = 7/16 = 0.4375$ inch; $a = 4 - (1/2\sqrt{3})(3/16) = 3.94587341$; $K = c/\sqrt{3}a = 0.0640139$; and $K^2 = 0.0040978$. Substituting these values in equation 15, obtaining values of the logarithms and arc tangents from the 15-place Works Project Administration tables, and effecting all computations on an electric calculating machine yields $L = 1.054$ abhenrys per centimeter of bus length. Multiplying this value by 3.048×10^{-6} yields $L = 3.21 \times 10^{-6}$ millihenrys per foot of bus length.

Corroboratively, check of this value against corresponding values of several busses of comparable current rating comprised of more conventionally arranged strap and channel conductors reveals that the just computed value for the nested 120-degree-angle bus to be about one-third to one-half as great as for these other conductors; hence the reactive voltage drop will be in the same proportion. This comparison reveals the considerable efficacy of the nested 120-degree-angle bus for low-voltage heavy-current duty where the reactive voltage drop must be minimized to obtain a specified permissible limit of voltage regulation, and also is in agreement with similar results advanced in reference 4, where the inductive reactance of a 3-phase 5,000-ampere finned 120-degree-angle bus had about 40 per cent of the inductive reactance of a similarly rated bus comprised of 7-inch double-channel conductors coplanarly spaced on 12-inch centers.

Appendix. Calculation of the Five Geometric Mean Distances

Calculation of the five geometric mean distances indicated in equation 14 is to be typified as follows. From page 327 of reference 16, the geometric mean distance D between the line segments RS and PQ of Fig. 4 is given by

$$\begin{aligned}(PQ)(RS)[2 \log D+3] = {} & \log (PR)\times \\ & [2(OP)(OR) \sin^2\theta-(PR)^2 \cos\theta]+ \\ & \log (QS)[2(OQ)(OS) \sin^2\theta-(QS)^2 \\ & \cos\theta]- \log (PS)[2(OP)(OS) \sin^2\theta- \\ & (PS)^2 \cos\theta]- \log (QR)[2(OQ)(OR) \\ & \sin^2\theta-(QR)^2 \cos\theta]- \sin\theta[(OP)^2 \\ & \text{angle } SPR-(OQ)^2 \text{ angle } SQR+(OR)^2 \\ & \text{angle } PRS-(OS)^2 \text{ angle } PSQ] \qquad (18)\end{aligned}$$

where θ designates the angle at the vertex O of Fig. 4, and the distances from one point on the line to another are given in parentheses.

To calculate D_{13} by use of this equation is shown as follows. With respect to Fig. 5, by equation 17 of reference 15, it is seen that

$$a^2 \log D_{13} = a(a-d/\sqrt{3}) \log D_{13''} + (ac/\sqrt{3}) \log D_{13'} \qquad (19)$$

On comparing Figs. 4 and 5, by aid of equation 18 the two geometric mean distances of $\log D_{13''}$ and $\log D_{13'}$ in equation 19 can be calculated. The computation is tedious but straightforward. In similar fashion, the other four geometric mean distances of equation 14 can be calculated; or else, as for $\log D_{11}$ and $\log D_{33}$, they can be written down from equations given in reference 16. For complete details see reference 31.

◆

Discussion

L. P. Lanigan (Chase Brass and Copper Company, Waterbury, Conn.): One of the important considerations of most a-c busses is of course the reactance voltage drop. When the bus is of considerable length and the current is relatively high, careful attention must be given to this factor. There are various methods of designing an electric bus so as to maintain the reactance voltage drop at a low value.

The 3-phase bus design consisting of 120-degree-angle conductors described in the paper provides an effective method of minimizing the reactance voltage drop. Although this is the most important advantage of such a bus, it has other desirable characteristics as pointed out by the author. The bending of the conductors to a 120-degree angle provides mechanical strength to withstand short-circuit forces. Its compactness minimizes space while the flat surfaces permit the connecting of branch circuits.

The copper suppliers can furnish the straight lengths of flat rectangular bus bars to the bus fabricating companies. The latter can then bend them into the required shapes and complete the assembly of the bus. It would appear that consideration could be given to this type of bus when the bus is long and the current is quite high so as to maintain the reactance voltage drop at a low value.

Donald H. Sandell (Aluminum Company of America, Pittsburgh, Pa.): We believe this is a worth-while paper which makes a definite contribution to the store of knowledge that bus designers can use in their work.

There are many installations in our company where sector bus (as we call it) is used and we have knowledge of some outside of our company. In addition to generating station and industrial use, this bus is used to distribute power to load centers in large commercial buildings. Our test data deviate in some minor respects from the conclusions in the paper, but are not inconsistent with the general relationships given in the paper. For instance, our tests indicate that the nonuniform current distribution in the conductors is significant as evidenced by the ratio of a-c to d-c resistance of from about 12 to over 20 per cent.

Temperature rise measurements also indicate significant nonuniform current density. It must be admitted, however, that these tests were conducted on practical sector bus shapes and not on the ideal uniform shapes as shown in the paper.

C. M. Siegel (University of Virginia, Charlottesville, Va.): In view of the increasing importance of busses comprised of 120-degree-angle conductors, this paper should be of appreciable value to engineers concerned with the design of busses having low reactance and considerable mechanical rigidity. The authors have given a clear development, leading to results that are readily applicable to the rational design of a bus having the subjective configuration. The utility of the results is enhanced by the authors' discussion and references which justify the assumptions and approximations that are necessary for a tractable analysis.

Equation 15 of the paper is well suited for simplification by expansion in a power series. If $K \ll 1$, then power series expansions of the terms involving the logarithms and arctangents, about $K=0$, are rapidly convergent. Since in practice the dimension a, Fig. 2, will often be much larger than the dimension c, thus giving $K \ll 1$, such expansions followed by collection of terms involving like powers of K will reduce equation 15 to a very simple form.

Expansions of the terms involving the logarithms and arctangents are facilitated by the following relations[1]

$$\log (1+x) = x - x^2/2 + x^3/3 - \ldots \quad (x^2<1 \text{ and } x=1)$$

$$\tan^{-1} [(m+nx)/(p+qx)] = \tan^{-1}(m/p) + x(np-mq)/(p^2+m^2) + (x^2/2!)2(mq-np)(mn+pq)/(p^2+m^2)^2 + \ldots$$

Applying these to the various terms (excepting the first logarithmic term) of equation 15, multiplying polynomials where indicated, and collecting coefficients of like powers of K yields

$$L = (\pi/8\sqrt{3}) + 0.375 \log 3 + 1.5K^2 \log K + K[(2\pi/\sqrt{3}) + 1.5 \log 3 + 1.125 \log a] + K^2[-0.5625 - (3\pi/4) + 0.375 \log a + 0.75 \log 3] + \ldots \quad (20)$$

A check on the validity of this equation is effected by noting that the first two terms (to which the right side reduces when $K=0$) agree with equation 17 of the paper. This leads us to note that the inductance is expressed in equation 20 in terms of the value for coinciding flanges ($c=0$, $K=0$) plus departures from this value due to separation ($c \neq 0$, $K \neq 0$) between the flanges.

Simplifying the combining the constant quantities in equation 20 yields, finally

$$L = 0.63871 + 1.5K^2 \log K + K(5.2755 + 1.125 \log a) + K^2(-1.0989 + 0.375 \log a) + \ldots$$

Applying this to the illustrative example of the authors' paper and effecting computations with a slide rule, we obtain

$$L = 0.6387 - 0.0169 + 0.4365 - 0.0024 + \ldots = 1.056 \text{ abhenrys per centimeter of bus length}$$

This agrees with the value in the paper.

We see, in this example, that neglecting the value -0.0024 associated with the last term increases the error by less than 0.25 per cent. Hence it follows that, for busses having $K \ll 1$, sufficient accuracy for engineering purposes is obtained by neglecting terms involving K to more than the first power (excepting the log K term).

1. TABLES OF INTEGRALS AND OTHER MATHEMATICAL DATA, **H. B. Dwight.** The Macmillan Company, New York, N. Y., 1947, equations 601 and 38.

J. W. Maier and **T. J. Higgins**: Mr. Lanigan has very aptly summarized the essential electrical and mechanical advantages of the 3-phase 120-degree-angle bus, as viewed by a practicing bus designer. His remarks both substantiate and compliment similar statements by the authors at various points in their paper.

The authors are more appreciative of Mr. Sandell's complimentary appraisal of the general merits of their paper. Additively, they are pleased to have Mr. Sandell's statement and reference as to successful use of the 3-phase 120-degree-angle bus for power supply to load centers of commercial buildings, a possible and important use not specifically remarked in their paper.

Mr. Sandell's remark that tests reveal that skin and proximity effects produce an a-c resistance somewhat greater than the d-c resistance, with a resulting slight nonuniform current-density distribution as evidenced by temperature rise measurements, is in accordance with a similar statement in the beginning of our paper. Further, the values he cites confirm other of our remarks: that the actual increase of resistance will not be large; and that in view of such slight increase (which indicates a corresponding relatively small shift from uniform current distribution), the values of inductance calculated on the assumption of uniform current distribution will yet be substantially the same as for uniform distribution.

It is of interest to note that these facts for the rather complicated 120-degree-angle geometry are in accord with similar variations in conductors of circular or annular cross section whereof the skin-effect changes of inductance and resistance with increase of frequency can be calculated exactly. Moreover, as inductance decreases with increases of frequency, a value calculated on the assumption of uniform current distribution will be slightly higher than the actual value; whence the calculated value will be on the optimum side, as regards use in design.

The authors are indebted to Dr. Siegel for an admirable supplement to the analysis of their paper. By use of series expansions in terms of small parametric ratios of bus geometry, a technique successfully employed earlier in his work with one of the authors on double-channel busses,[1,2] Dr. Siegel has advanced equations which enable very rapid and accurate slide-rule calculation of the desired inductance.

In conclusion, we extend our most sincere thanks for the valuable substantiative and illuminative comment advanced by the three discussers of our paper.

An Elliptical Polarization Synthesizer

G. H. FRIEDMAN
ASSOCIATE MEMBER AIEE

Synopsis: An electronic instrument is described which automatically determines the resultant polarization of two superimposed elliptically polarized waves when the polarization of the individual components is known. In addition, a study of the effect of ground pulse contamination on polarization data obtained by sounding the ionosphere is presented. The study serves to demonstrate the usefulness of the instrument.

IN THE investigation of the properties of the ionosphere through the study of the observed polarization of ionospherically reflected low-frequency radio waves, it often becomes necessary to compute the resultant polarization of two component waves. More often, the two components are related magneto-ionically, but occasionally problems arise in which the components are more generally related or not related at all. Methods are available for computing this resultant either analytically or graphically when the polarization, relative amplitude, and phase difference of the two component waves are known.[1,2] Although these methods are not complex, they tend to become lengthy and tedious whenever many computations are necessary and, very often, the physical significance of the results tends to become obscured.

In conjunction with a program of ionospheric research conducted at the Ionosphere Research Laboratory, an instrument has been built which performs the computation for obtaining the resultant polarization of the two component waves automatically.[2] This resultant is graphically represented on the screen of a cathode-ray oscillograph. The parameters of the ellipse, angle of the tilt of the major axis, axial ratio and rotational sense may be observed and measured directly on the oscillograph screen. The advantages of using such an instrument are twofold. In addition to the saving of time and labor which is consumed in computational methods, it is possible for the operator to reproduce the observed behavior of an ionospherically reflected echo and thereby study, in a semi-quantitative way, the variation of the individual component waves. This leads to a fuller understanding of the physical processes involved.

The Elliptical Polarization Pattern

That property of electromagnetic radiation known as polarization, the process by which the variations of the electric and magnetic intensity of a wave are confined to a definite pattern, is familiar enough so that very little detailed discussion of the concept need be given here. It will be sufficient to recall that the polarization pattern is a graphical representation of the locus of either the electric or magnetic intensity vector of the polarized wave. For single-frequency radiation that locus is, in general, an ellipse. It is well known that the vector describing the ellipse may be resolved into sinusoidally varying components in space quadrature.

A set of rectangular co-ordinate axes, x and y, and a typical polarization ellipse are shown in Fig. 1. The value of ρ_1 represents the ratio of the amplitudes of the sinusoidal space quadrature components along the x and y axes. A second set of rectangular co-ordinate axes can be defined to coincide with the major and minor axes of the ellipse. The angle of tilt of the ellipse ψ is defined as the angle between the two sets of co-ordinate axes. The angle θ is defined as the angle whose tangent is the ratio of the length of the minor axis to the length of the major axis. The quantities ψ, θ, and the direction of rotation of the vector serve to define completely the ellipse, neglecting absolute magnitudes. It can be shown that these three parameters may be simply written in terms of the ratio ρ_1 and the phase difference between the sinusoidal components along the x and y axes.

When a sinusoidal voltage is applied to the vertical deflection plates of a cathode-ray tube and another sinusoidal voltage of the same frequency is applied to the horizontal deflection plates, an elliptical Lissajous pattern will, in general, be traced out on the cathode-ray tube screen. If desired, this Lissajous pattern can be caused to be an exact representation of the elliptical polarization pattern of some particular electromagnetic wave. To do this, the ratio of the amplitudes and the phase difference of the two voltages

may be set equal to the same parameters of the electric or magnetic intensity space quadrature components.

Finding the resultant polarization pattern of two superimposed waves when the polarization of each is known is essentially a process in which the corresponding space quadrature components of the appropriate vector for each wave are added by means of the theorems of trigonometry. Here again, to produce a Lissajous pattern which represents the polarization of the two superimposed waves, it is merely necessary to impress voltages upon the deflections plates of the cathode-ray tube which correspond to the sums of the wave quadrature components.

The General System

In a relatively straightforward manner, it is possible to construct an electronic instrument which will provide the four sinusoidal voltages necessary to represent the space quadrature components of the two polarized waves it is desired to study. This is done by suitable use of attenuators, phase shifters, switches, and amplifiers. The corresponding pairs of these voltages may then be added and the resultant signals used to energize a cathode-ray oscillograph. The functional operation of such an instrument is shown in Fig. 2.

The attenuator A and the phase shifter α, shown in Fig. 2, provide a means for inserting quantities which account for the relative amplitude and total phase difference between the two waves whose resultant polarization pattern is to be found. The total channel switch enables the operator to apply these quantities to either of the two ellipses which are being formed. The attenuators ρ_1 and ρ_2 are provided in one line of each of the two ellipse forming channels so that the proper value for the amplitude ratio of the two voltages used to form each ellipse may be inserted. By proper setting of the attenuator axis switches, these attenuators may be used in either of the two lines of its channel.

This feature is necessary since, to be able to form an ellipse with any given axial ratio and angle of tilt, the amplitude of one of the quadrature components must be from zero to infinity or, as is more practical, the magnitude of each of the quadrature components must be varied with respect to each other. The channel selector switch provides a means for viewing each of the component ellipses which are formed or their resultant, as desired.

To define completely the polarization pattern, it is also necessary to specify the direction of rotation of the vector or of the corresponding cathode-ray tube trace. On the instrument that was built, this determination was made possible by a circuit which shifts the vertical deflection

voltage 90 degrees lagging in phase. This phase-shifted voltage is then coupled to the intensity modulation amplifier terminals of the oscillograph. When this is properly done, half of the elliptical pattern will be blanked out. A study of Lissajous patterns will show that, for a pattern produced by a trace rotating in the counterclockwise, or left-handed, direction, only the left-half portion of the pattern will remain visible. Although this method for determining the direction of rotation serves satisfactorily, a somewhat simpler scheme has been suggested to the author. By modulating the intensity of the trace with pulses possessing a sharp rise and exponential decay, a bright spot with a tail will be produced. The direction in which the tail will point will indicate the direction of rotation.

A typical polarization pattern is shown in Fig. 3 and a modulated pattern in Fig. 4.

Circuit Details

Fig. 5 is a schematic diagram of the more important circuits of the elliptical polarization synthesizer which was built. Standard resistance-capacitance coupled amplifiers and cathode followers are used throughout. The attenuators used are simple potentiometer voltage dividers. Of particular interest, perhaps, are the continuously variable linear phase-shifter circuits.[3] These employ resolver-type synchros or, simply, resolvers. Resolvers possess a rotor with a single winding and two stator windings in space quadrature. When the rotor winding is energized by a

sinusoidal voltage, voltages are induced in the stator windings which are in time phase with the energizing voltage. However, the amplitude of the voltage induced in one of the stator windings is proportional to the sine of the angle that the rotor makes with some reference position. The voltage amplitude induced in the second stator winding is proportional to the cosine of the same rotor angle. The two stator voltages are connected at opposite ends of a series resistance-capacitance network where $R\omega C=1$. The voltage at the junction of the resistor and capacitor is a constant amplitude signal whose phase varies linearly and continuously with the angular position of the resolver rotor.

Experimental Results

A study was conducted to determine the possible effect of ground pulse contamination on the observed polarization of a 150-kc-per-second pulsed signal reflected from the ionosphere. This was done to demonstrate the usefulness of the instrument described in the foregoing and, in addition, to obtain information pertaining to the study of the ionosphere.

Ground pulse contamination may arise from the fact that the polarimeter system for recording the polarization of echoes returned from ionosphere may require the leading edge of the echo which is measured to be located very near the trailing edge of the ground pulse, along the time axis, at certain times.[4] Since the recording equipment chooses a particular portion of the time axis by a suitable gate, it is conceivable that a portion of the ground pulse in contained within the gate.

This problem was set up on the elliptical polarization synthesizer, Fig. 6, in such a way that various magnitudes of ground pulse could be added to the returned echo polarization with different phases and relative amplitudes between the two. The echo polarization chosen for the study was typical of what might be expected under conditions where pulse overlapping is possible.

The problem was to determine whether or not the addition of various amounts of ground pulse could produce the phenomenon locally called flip-overs. This is the rotation of the major axis of the net ellipse into the second and fourth quadrants. Flip-overs cannot be explained by simple theory for the frequency of operation (150 kc per second) and geographical location (State College, Pa.) if a pure magnetic-ionic wave is being returned.

By varying the magnitude of the ground pulse polarization pattern and by varying the phase difference between the ground pulse and the echo signal, the effect on the resultant polarization was determined. Curves of this variation are plotted in Figs. 7 and 8. The curves indicate two things that should be evident in the experimental results if there is contamination of the returned echo: 1. rapid fluctuations in tilt angle with a spread of approximately 40 degrees around noon for a ground pulse amplitude one-half that of the echo amplitude; 2. discontinuities in the diurnal and seasonal plots of tilt angle.

The existing data indicate that the fluctuations in angle of tilt are not very rapid with the spread indicated and there are no discontinuities in the diurnal and seasonal plots.[5] Consequently, it may safely be said that ground pulse contamination does not cause the so-called flip-overs to the extent recorded experimentally.

The particular polarization pattern chosen to represent the echo is one possessing an angle of tilt ψ equal to 74 degrees and axial ratio represented by the angle θ equal to 30 degrees, and which possesses a positive sense of rotation. The ground pulse polarization pattern, corresponding to the actual observed

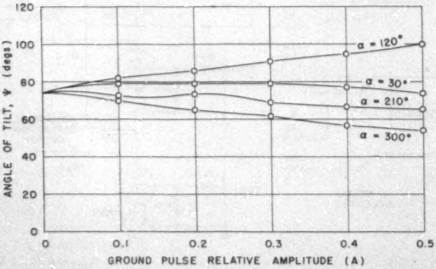

Fig. 7. Variation of angle of tilt ψ for contaminated echo

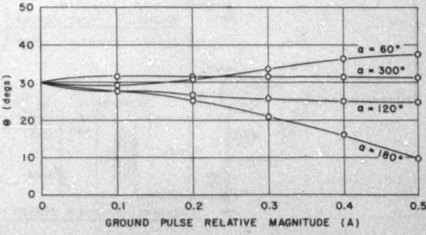

Fig. 8. Variation for Θ for contaminated echo

pattern, is one with an angle of tilt ψ of 11 degrees, θ equal to 30 degrees, and positive rotation. Data were taken using the elliptical polarization synthesizer in the following manner. With the channel 1 and 2 controls set to produce the echo and ground pulse patterns respectively, A, the relative magnitude of the ground pulse was increased from zero to 0.05, 0.1, 0.2, 0.3, 0.4, and 0.5 for a constant value of α, the phase difference between the waves. Readings were taken in this way for values of α at 30-degree intervals from 0 to 360 degrees. Four curves are included in each figure. The uppermost and lowermost curves are for those values of α for which the widest variation of ψ or θ occurred. The other two curves in each figure were included to indicate the rate at which the variation changes for different values of α.

In connection with this study, all of the values for the resultant polarization for $A=0.5$ and $\alpha=0$ to 360 degrees were determined by graphical computation. These values were compared with the instrumentally obtained results. In general, it may be said that the results obtained by use of the instrument are well within the experimental error of the actual ionospheric recording equipment. Values obtained for ψ are within ±6 degrees of the computed value and the values obtained for θ are within ±4 degrees of the computed value.

Discussion

J. M. Watts (National Bureau of Standards, Washington, D. C.): This paper describes a type of analogue computer. The desired solutions can be quickly arrived at graphically by the traditional circle-diagram method of adding and subtracting 2-dimensional vectors. The accuracy would be as good as, or better than, that obtained by measuring an oscilloscope pattern.

However, it is probable that this instrument would be of some value as a classroom demonstrator in ellipse synthesis. The addition of two voltmeters and a phase meter in parallel with the oscilloscope inputs would improve the accuracy by eliminating the necessity of measurements from the screen. The two methods described for demonstrating the direction of rotation are well known, as is a third which consists of modulating the input voltage with a sawtooth voltage of suitable frequency and amplitude synchronized to a submultiple of the input frequency. Under this system the ellipse changes into an elliptical spiral whose beginning and end show the direction if the sawtooth slope direction is taken into account. This system is particularly easy to apply since the sawtooth sweep oscillator voltage of many oscilloscopes is externally available and may be used independently for the purpose.

G. H. Friedman: I appreciate the comments made by Mr. Watts who is quite correct when he states that more accurate graphical techniques are available for performing computations involving the addition of ellipses. This fact is mentioned in the beginning of the paper. However, in the particular application for which the elliptical polarization synthesizer was designed, close accuracy was neither required nor realistic. The polarization data which formed the basis of the studies being made were scaled from similar elliptical patterns produced on a cathode-ray tube screen by reflected radio waves. Thus, a part of the significance of the instrument described is that it represents an attempt to reduce the burden of trial-and-error computation by presenting the results of that computation in a visual form directly related to experimentally observed phenomena.

Surface and Volume Dielectric Losses

A RELIABLE and convenient system has been devised for measuring large numbers of specimens to detect changes in dielectric constant and dissipation factor due to exposure to controlled conditions of temperature and humidity. A group of four plastic materials consisting of a molded mica-filled phenolic (MFE), a glass silicone laminate (GSG), polytetrafluoroethylene (PF) and polyethylene (PE), were selected for study over the frequency range from 60 cycles per second (cps) to 100 megacycles per second (mc). Measurements of alternating current surface and volume conduction losses, and d-c surface and volume conductivity were made, along with measurements of dielectric strength and flashover strength.[1] The effect of humidity and temperature on these electrical quantities was a major objective in an extensive program. Earlier work at The Johns Hopkins University had greatly stimulated the present interest in the measurement of surface conductivity.[2,3] Although the earlier efforts were made with direct current only, it was generally considered that the work could be extended to the a-c case through the use of a high-voltage Schering bridge. This has been accomplished, data having been obtained at 60 and 1,000 cps. Such measurements are possible with a high-voltage Schering bridge up to 100,000 cps. Using other types of networks, the surface measurements were also taken at 2, 18, and 100 mc. The volume determinations of dielectric constant and dissipation factor were made at the same frequencies. Perhaps the most stringent requirement met in these tasks was that all specimens had to be mounted in holders and measured on location without being disturbed during their 6-month exposures to various conditions of temperature and humidity.

Specimens and Electrodes

To investigate fully both surface and volume phenomena, four types of painted electrode patterns were used, as shown in Fig. 1. Electrode 1, referred to as the

This work was performed under Contract *DA-36-039-sc-42478* which was sponsored by the Army Signal Corps. W. F. List and J. S. Smith contributed to the design and development of circuits. Acknowledgment is made to F. L. Schaff and A. Prock for the measurement of the electrical properties of the specimens involved in a lengthy schedule. L. J. Frisco offered timely advice and constructive criticism in accomplishing the work and preparing this report.

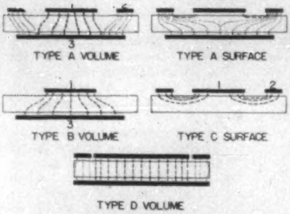

Fig. 1. Electrode patterns on loss specimens showing approximate field shapes

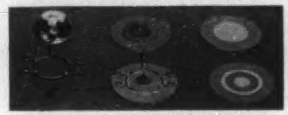

Fig. 2. Type-A loss specimen with stainless steel electrode

measurement electrode, is 1 inch in diameter. Electrode 2, the ring electrode, engages a painted ring which has a $2^1/_4$-inch outside diameter and a 2-inch inside diameter. Electrode 3, the large electrode, is $2^5/_{16}$ inches in diameter.

A type-*A* specimen employs three electrodes which may be connected for either volume or surface measurements. For volume measurements the ring electrode serves as a guard, so its potential is maintained very close in magnitude and phase to that of the measurement electrode. The large electrode is connected to the high-voltage source and the resulting field pattern is somewhat as shown in Fig. 1. The painted patterns and stainless-steel electrodes for a type-*A* specimen are shown in Fig. 2. For surface measurements the potentials of the ring electrode and the large electrode are interchanged, and the large electrode then becomes the guard, while the ring electrode is connected to the high-voltage source. The field pattern shown in Fig. 1 illustrates the approximate stress distribution. The current along the surface may become quite large in a humid atmosphere in the case of some materials. It was found that measurements made with direct current, 60 cps, 1,000 cps, and 2 mc gave reliable results for both surface and volume with the type-*A* specimens. At higher frequencies it was necessary to use two electrode specimens because capacitance effects made it impractical to maintain a third electrode at the proper potential.

The type-*B* specimen employs electrodes 1 and 3, the latter being connected to the high-voltage source. This type of specimen is suitable for the measurement of volume properties from 2 mc to 100 mc. A guard ring is not required for the high-frequency volume measurements because the effects of surface loss have proved negligible for such an arrangement. At high frequency even a leakage path of 10 megohms would have a negligible effect when it is associated with a dielectric part which has a capacitive reactance of perhaps 100 ohms. The Q of such a component would be 10^5 and therefore would not be likely to compromise the functioning of a circuit. By contrast, a 10-megohm leak across the same capacitive element at 60 cps would cause a very large phase defect angle in the circuit. In the case of materials which had no measurable surface conduction, the type-*B* sample could be used to check the volume measurements of the type-*A* sample at 60 cps, 1,000 cps, and 2 mc.

The type-*C* sample employs electrodes 1 and 2 and is suitable for surface measurements at 18 and 100 mc. In this case the ring electrode is connected to the high-voltage source. This type of specimen also provided a qualitative check on the surface measurements of the type-*A* specimen at 60 and 1,000 cps.

The use of these three types of specimens made it possible to cross check various observations pertaining to the surface and volume behavior of the four materials. Because the field patterns involved in the *A*, *B* and *C* specimens are admittedly complicated, a considerable amount of calibration was necessary. For this purpose the type-*D* specimen was used to evaluate all materials at 60 and 1,000 cps. This conventional specimen, shown in Fig. 1, has a 3-inch diameter measurement electrode with a very close fitting guard ring, thereby affording the simplest geometrical configuration. In this manner all types of specimens were reduced to an equivalent geometry at 60 cps, which was confirmed at 1,000 cps. This geometric equivalence is independent of frequency over the chosen frequency range, since the specimen dimensions were insignificant compared to wave length, even at 100 mc.

Conditioning Cabinets

Storage under nine conditions of exposure took place in specially constructed cabinets the lids of which were equipped to hold 36 specimens for loss measurements, so that variations in properties could be followed without interruption for periods up to 6 months. Fig. 3 shows a typical lid with various types of specimens mounted; actually six positions were usually taken up with air capacitors for the purpose of checking measuring equipment. All such lids were equipped with rectangular screen baskets, to shield the specimens from stray electrical effects during measurement. This entire assembly was placed on a rubber gasket which provided guard insulation and sealed the cabinet as well.

Fig. 3. Conditioning cabinet lid with loss specimens mounted

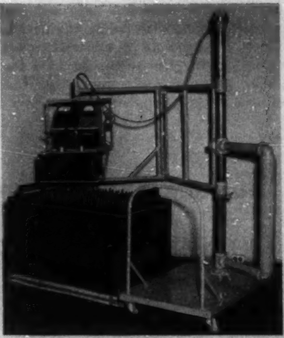

Fig. 4. Conditioning cabinet and mobile measurement unit

The cabinets had an additional 4 cubic feet of storage space below the lid and guard screen for other types of speci-

mens. Fig. 4 shows a cabinet under the mobile measurement equipment. The nine conditions of exposure are shown in Table I.

All cabinets were copper-lined and equipped with circulating blowers and temperature controls. Humidity in some cases was controlled by maintaining a layer of water in the bottom of the box at the desired wet-bulb temperature. For the 25C, 20-RH condition, it was necessary to tap a dry compressed air supply and feed one of the cabinets at a slow but steady rate. Conditioning at −55C was accomplished by use of a 2-stage-compressor deep-freeze cabinet. The lid containing the loss specimens was constructed in a manner similar to all others except that it was 2 inches thick and was extremely well insulated thermally. Except during periods of measurement, the outer metal-clad lid of the unit was kept closed. Appreciable frosting at the electrical entry points caused no serious difficulty during measurement procedure, since frost apparently has a reasonably high dielectric strength.

Methods

The high-voltage Schering bridge used during the investigation was constructed for the particular task. Although regular routine called only for measurements at 60 and 1,000 cps, particular points of interest sometimes caused a specimen to be traced up to 100,000 cps with this device. It was found that the flexible guarded cables to the specimens could be 8 feet long without sign of error. The bridge is conventional in most electrical details except that the guard circuit was of unusually low impedance both in its balancing network and high-voltage coupling. This circuit was made "stiff" to offset any effects of surface leakage on guard insulation in the more humid conditioning cabinets. Since the specimens had to suit higher frequency purposes as well, their capacitance was of the order of 10 micromicrofarads. Some accuracy was sacrificed by using such small specimens; with 1,000 volts applied to the bridge, the lower limit of dissipation factor detection was 0.001.

At 2, 18, and 100 mc another type of network was used for the measurement of dielectric constant and dielectric loss of the specimens in the cabinets. This network for some whimsical reason became known as the Beechnut circuit; it has been described in its preliminary development.[4] Inherently it has about the same sensitivity as a *Q*-meter, but rather than measure resonant rise of voltage in a series circuit, it measures residual current in a parallel resonant circuit. Its great advantage is that in working around conditioning cabinets, all metal enclosures surrounding the specimens become an approximate low-voltage guard and thus intercept loss currents arising from wet or faulty bushings. In extending the use of the device up to 100 mc, it was found advisable to make the adjustable quantity in the parallel resonant circuit the inductance rather than the capacitance.

An important feature in the use of this circuit at 2, 18, and 100 mc, was mobility. The network had to be brought close to the specimens mounted in each conditioning cabinet. Fig. 4 shows a 2-mc Beechnut network suspended and in position for a series of measurements. The mechanics of connection to each specimen terminal are quite exacting. Contact resistance must be avoided at these terminals and also at the junction surfaces of the mounted specimens. Errors leading to exceptionally high values of dissipation factor at 100 mc were ultimately traced to contact resistance. The air capacitors in each conditioning cabinet covered the range of all measurement devices so that test location or grounding condition could not change capacitive calibration without notice. Further, these capacitors provided a zero loss reference at all frequencies.

The voltage applied to the 1/8-inch thick specimens, in measuring dielectric constant and dissipation factor was 1,000 volts at 60 cps but less at higher frequencies. At 2 and 18 mc it was 125 volts, while at 100 mc it was kept at 50 volts. This tapering of voltage with respect to frequency was consistent with maintaining ample sensitivity and at the same time avoiding changing the internal temperature of a specimen during measurement. At 2, 18, and 100 mc the power supplies were about 60-watt output. At lower frequencies the bridge supply was capable of delivering over 1,000 watts.

Volume Properties

Table II gives the initial values of dielectric constant and dissipation factor of the four materials over a wide range of temperature and frequency. In many cases 1 hour elapsed in letting the specimens come to temperature equilibrium. Using the rather small specimens previously described, PE and PF showed no detectable dissipation factor initially or with prolonged exposure to various conditions. Among laminated materials, GSG may be considered a low loss material throughout the range of initial tests.
